In the main the answer to these questions must now be, No. For a generation or more the traditional picture has been undergoing disintegration. Medical historians have naturally sought to preserve an exquisite story, but the plain truth is that advance in knowledge has at last made a revision of the traditional view inevitable. For sheer brevity we set forth the present state of the extremely complex Hippocratic problem in catechismal form. There is no need to treat the answers here given with the respect that are accorded to certain other catechisms. They do represent, however, the sound working probabilities.

A Catechism on the Hippocratic Problem

Was there a physician, Hippocrates of Cos, who flourished about 400 B.C.? Yes, certainly. He is mentioned in two dialogues by his younger contemporary Plato, briefly, but with respect.

Did Hippocrates of Cos write any of the works in the Hippocratic Collection? There is no evidence of value that he wrote any of them. There is some little evidence that he wrote nothing at all.

Are there remains on Cos that can be linked with Hippocrates?—No. The temple of Aesculapius there has nothing to do with Hippocrates. The Aesculapian cult did not reach the island till after the death of Hippocrates. Objects from Cos suggest a rather low civilization there in Hippocratic times. A number of inscriptions at Cos show, however, that a medical school flourished there some 200 years after his death. Perhaps this school was related to the rise of the tradition that the Hippocratic Collection was his work.

When and where was a Hippocratic Collection first linked with the name of Hippocrates?—Probably about 300 B.C., and almost certainly at Alexandria.

Why were the books of the Collection labelled Hippocratic?—A brief answer must over-simplify. The Alexandrian physicians were interested in dietetics. They sought texts on a subject. The great library provided them. Some of the MSS. mentioned Hippocrates as the oldest exponent of dietetic teaching. Thus MSS. bearing his name became specially valuable. Demand created supply. Dealers were naturally not slow to discover MSS. of "genuine works of Hippocrates." Hence the nucleus of the Collection.

Why did the Collection grow further?—Most of our knowledge of ancient medicine comes from Rome in the first century (Celsus, etc.) and second century (Galen, etc.). To writers of Imperial Rome the time of Socrates, Hippocrates, Plato and Aristotle—the fifth and fourth centuries B.C.—was a golden age. Thus the Hippocratic legend launched at Alexandria gathered momentum at Rome.

Have we any idea of how Hippocrates of Cos practised? We can guess by piecing together scraps from our knowledge of Greek life and from those parts of the Hippocratic Collection that are of the fifth or fourth century B.C.

What is the result of such guesses?—The medical man of those centuries was a craftsman. His status was a little higher than the tailor and the shoemaker, and comparable to that of the artist, but well below that of the sophist or soldier. Normally he travelled from place to place, settling for a while where he found practice active. Hence the extreme importance to him of what he calls "Pronoia," which is not quite what we call "prognosis" but is discerning a patient's trouble before he tells you—"spot diagnosis plus prognosis." By the fourth century, or earlier, larger Greek towns had appointed their own resident physicians. Possibly Hippocrates of Cos, having been first a wandering craftsman, settled down as a town physician.

Have we a portrait of Hippocrates of Cos?—Surely not. His day artists hardly attempted what we call portraiture. The famous portrait-bust in the British Museum, often reproduced as of Hippocrates, is very much later and is of the S. Chrysippus (c. 280-206 B.C.).

These, dogmatically expressed, are among the general results of modern research on Hippocrates and on Cos. Some are more reliable than others. Collectively they provide a picture of Hippocrates very different from the traditional. There is at least the consolation that the fighting on Cos is not likely to have destroyed the embodiment of any sacred medical tradition.

C.S.

Correspondence

R.M.B.F. Christmas Gifts

SIR,—It is my custom each autumn, through your column, to invite my medical colleagues to take their part in the Christmas Gifts Fund of the Royal Medical Benevolent Fund. This scheme, so generously supported by many, has become very remarkable, as it has been the means not only of bringing to many old and lonely people a gift of friendship and sympathetic understanding at Christmas time, but it has also given many of your readers an insight into the great work which the Royal Medical Benevolent Fund is doing daily helping medical colleagues, or the widows and children of deceased medical practitioners who are in financial difficulty.

We look upon the Christmas gift of £2 to each beneficiary as something "extra," but I must emphasize that the regular allowances have to be paid throughout the year. New subscribers are very urgently needed for our general funds, surely it is for the present generation of practitioners to take up their share in a work which is a common professional inheritance and tradition. It is not difficult to realize work which brings happiness and comfort. A Christmas gift of £2 brings to an aged doctor, an aged widow, or daughter living alone, possibly suffering from illness or infirmity. We ourselves know the difficulties and discomforts of our own lives caused by the present war. May I appeal, Sir, very earnestly on behalf of those who have suffered so much more than ourselves?

I venture to make this letter a *twofold* appeal: (a) to regular subscribers to send their "extra" for the Christmas Gifts Fund; (b) to all others, to show their practical sympathy.

y becoming subscribers to our general funds. I do not ask for large contributions.

Christmas gifts donations should be marked "Christmas gifts," and all cheques made payable to the Hon. Treasurer, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, S.W.15.—I am, etc.,

THOS. BARLOW,
President.

Books for Prisoners of War

SIR.—Members responding to my appeal at the Annual Representative Meeting should send their cheques to the Hon. Treasurer, Medical War Relief Fund, B.M.A. House, Tavistock Square, London, W.C.1, making them payable to him and enclosing a slip to say that the gift is intended "for medical books for prisoners of war."—I am, etc.,

JOHN W. BONE.

Early Recognition of Cancer

SIR.—I am glad that Mr. Malcolm Donaldson (Sept. 25, p. 402) has drawn attention to the excellent propaganda work already carried out by the British Empire Cancer Campaign in this vital sphere. I am not unaware of such efforts, but a figure of 58,000 addressed in 4 years is perhaps as powerful an argument as I could wish to see brought to show the inadequacy of our achievement so far.

I have before me a copy of the Annual Report of the Campaign for 1942—the total income about £45,000. In such exigent circumstances, all praise to them for their very real achievements. But surely the scale of things needs to be changed when we begin to implement the Cancer Act. Would it not be a sound financial investment, viewed even from the narrow economic angle, to start off not with £45,000 but with £450,000 in a real nation-scale effort to put cancer "on the map"? I would like to see the subject publicized by every modern method and introduced by a talk on the wireless after the Sunday 9 o'clock news by, say, Lord Horder, followed by a regular series of talks; short films at all local cinemas to show that pessimism about cancer is out of date; skilful advertisements in the Press on the lines of the current V.D. campaign; as well as the very necessary patient slogging away in the manner mentioned by Mr. Donaldson. Incidentally, it is pleasing and important to have his testimony about the bugbear of cancer phobia.

Obviously nothing less than a Governmental grant will be adequate for all this. Our plans should match the magnitude of the problem, and the time to begin is now.—I am, etc.,

JOSEPH WALTER,
Assistant Medical Director, Sheffield Radium Centre.

Sterility and Impaired Fertility

SIR.—The official census data do not yield any direct information concerning the frequency of sterility (childlessness) or impaired fertility (small number of children). Nearly all information in this field springs from the general experience and the specific efforts of individual workers—mostly clinicians interested in the treatment of involuntary sterility. The following summary reflects the views formed by British and American investigators.

1. About one-tenth of all marriages remain childless. It has not been suggested that there are class differences which would reveal themselves without specific statistical investigations. Childless marriages among working-class patients are common.

2. Permanent childlessness is rarely deliberate. This conclusion is based on the experience of medical practitioners and on specific investigations. Thus inquiries were made among industrial workers in order to ascertain how many of the married but barren women were deliberately childless. This inquiry was conducted by a doctor who interviewed personally every woman; and the inquiry was appropriate, since the childless women numbered up to 18% of groups (consisting of about 50 women each) questioned. Similarly another investigator inquired into the history of about 70 childless middle-class families who had not applied for advice. It appears that in about 90% of childless couples who have been married for at least five years the absence of children was caused by impaired reproductive power (low fecundity).

3. Furthermore, such inquiries among patients who did not request advice for sterility show that in at least 60% of one-child couples (numbering more than 100) married for more than five years, further conceptions were either desired or not deliberately prevented. Clinical

experience extending to many hundreds of cases and investigations among working- and middle-class women indicate that the small family (two children) is also often due to low fecundity, and that fecundity tends to fall after the first or second confinement.

4. Data collected by individual clinicians and extending to over 4,000 cases and by clinics show that birth control, although applied at times by the great majority of the population, is rarely (in about 5% of young couples) intended to procure permanent barrenness. Furthermore, effective methods of birth control are usually sought among the working class only by women who have had one or more children. One of the statistical expressions of this fact is that in one group (numbering more than 200 women) of regular users of birth control the average number of children was higher than in a comparable group of women using the same methods intermittently. Further investigations show that the contraceptive methods most commonly used by the industrial population are notoriously unreliable (coitus interruptus or soluble pessaries); their seeming success, to which many working-class women attribute the small size of their families—i.e., 3 children in fifteen years of marriage—can be shown to reflect lowered fecundity in at least one-third of the cases (about 100) investigated.

5. Considering all available information it seems that in 60 to 90% of all barren and one-child couples lowered fecundity (involuntary factors) is involved. Lowered fecundity is also often found in couples with two or more children. But its practical significance is less than in the one-child families because the use of effective methods of birth control increases with the size of the family.

6. This widespread infecundity of the population is due in part to low female fecundity, particularly to conditions which tend to develop after confinements or miscarriages. But low reproductive power in men is very common; about 60% of husbands of childless women are either incapable of reproducing offspring or fail to attain a level of fecundity which would make conception easy to achieve (data from about 2,000 cases and American findings). Similarly the husbands in one-child families are often of low fecundity. Examination of about 100 volunteers (medical university students, professional men) confirms the view that average male fecundity is much lower than is commonly assumed. It appears to be definitely impaired in at least one out of five men examined. The subjects examined were mostly men in good general health.

7. Nearly 90% of the middle-aged childless women—i.e., the last generation of married women—of the industrial groups interrogated in inquiries had accepted their fate without seeking specific help from any doctor or clinic. The remaining women sought advice; but in less than 5% was adequate or even relevant advice given. Middle-class women seek advice much more frequently. In the great majority of cases examinations and advice still tend to be limited to the wife: recognition of the common male responsibility is relatively rare.

8. On the other hand the few specialized clinics which at present give advice on sterility are sought out by increasing numbers of women. Of the present generation of potential mothers one Glasgow hospital which maintains a sterility clinic (for women only) admitted 303 cases in 1938 and 505 cases in 1942. A similar increase of attendances has also been seen in others of the few clinics in this country which supply adequate facilities for the diagnosis and treatment of sterility. The interest shown by childless men is of a less active kind, but refusal to undergo examination is rare in childless or child-poor men (under 5% in hospital practice). A consideration of all available data strongly suggests that the barren and the very small family reflect lower fecundity rather than excessive unwillingness to reproduce. This being so, no effort to solve the problem of the decline in the population can be considered satisfactory unless it recognizes the necessity for providing facilities for the skilled diagnosis and treatment of all grades of infecundity.

Artificial Respiration

SIR.—It may help Prof. Cordier (*Journal*, Sept. 25) in his quest if I give him some of the results of an experiment suggested by and carried out on Squad. Ldr. E. A. P. This adult of 30 was anaesthetized deeply, an endotracheal tube of large bore passed, and the space between the outside of the tube and the trachea made air-tight by an inflated cuff. By means of a hand-bellows respiratory exchange was exaggerated, CO₂ washed out, and a state of apnoea induced. I would

confirm Water's observation (*Anesth. & Analges.*, 1936, 15, 151) that "an apnoeic patient under deep anaesthesia stimulates the candidate for resuscitation by artificial respiration." The endotracheal tube was connected to a recording tambour by Dr. Stuart Cowan and artificial respiration carried out by Dr. Mushin by many of the recognized methods. It is hoped to publish the full experiment shortly. In this case Eve's rocking stretcher method, with the patient prone, rocked through 90 degrees, gave an exchange of 580 c.cm.; Silvester's method, 400 c.cm.; and Schäfer's, 340 c.cm.—I am, etc.,

Oxford.

R. R. MACINTOSH.

Folding Trestle for Rocking a Stretcher

SIR.—Eve's method of resuscitation implying restoration of circulation, respiration, and warmth as distinct from our somewhat ineffective methods of artificial respiration led me to ask Mr. Holm, an engineer member of our casualty services, to devise a folding metal trestle which could be attached to an ordinary A.R.P. stretcher.

I enclose photographs of this appliance, which I feel is portable, simple, and therefore effective. The height from the ground is 32 in. As recommended by Surg. Lieut. Gibbins and in *First Aid in the Royal Navy*, B.R.26, it gives that full

range of movement which is so essential in restoring circulation. It can be operated by any onlooker, and I have therefore placed the operator at the feet, thus allowing the trained first-aid worker to direct the operation, to watch for signs of returning consciousness, and to endeavour to maintain warmth by hot-water bottles or other means at his disposal.

Since at any accident to which I have been ever summoned there have been more onlookers than desirable there should

be no question of any one person being fatigued from over exertion since "detailed volunteers" will provide an ample service.

This stretcher-cum-trestle is kept at our first-aid post, complete with blankets and triangular bandages, as a readily portable unit of our equipment, and is therefore easily accessible at all times.—I am, etc.,

Melksham.

D. LEIGH SPENCE,
District Medical Officer.

Psychology and the Common Cold

SIR.—In your issue of Oct 2 (p. 433) Dr. E. W. Braithwaite consulting psychiatrist to the Ministry of Health, ends his letter on the common cold with this sentence: "The specific factor is psychological; the microbic one secondary." You will note he says "is," not "may be." It is remarks such as this which tend to make the mass of medical men in this country distrust the psychiatrist with the homoeopath, the chiropractor, and the osteopath, and view with grave suspicion the power they are gaining in the advisory positions to the Ministry of Health and to the Forces.—I am, etc.,

Stratford, Berkshire.

LEONARD LESLIE, M.D.

Fibrositic Nodule

SIR.—Lieut.-Col. W. S. C. Copeman's article dealing with the aetiology of the fibrositic nodule (*Aug. 28, p. 263*) is a helpful contribution to the subject. The suggestion that not only influenza but many virus diseases are accompanied by pain radiating from small "myalgic" spots fits in well with experience of acute illness of various types. The further suggestion that the pain clears up but the "myalgic" areas do not sound clinical observation. There is a danger, however, that this explanation of one form of myalgia is so straightforward and so easily understood that it will tend to obscure the fact that fibrositis is a tissue reaction to many insults and traumas and that Copeman's article refers to only one aspect of its aetiology. Apart from certain rare syndromes, fibrositis of muscle and fascia is met with clinically under a variety of circumstances, sometimes taking a major part in the illness but as often being incidental, although none the less painful for that. Acute myalgia, the condition to which Copeman refers, is present in many acute illnesses; Dornholm disease is the epidemic variety.

Chronic fibrositis—perhaps better termed "myalgia"—occurs under four main conditions. First, as Copeman suggests, in an individual who has developed "myalgic" spots after acute infection; possibly undulant fever is the best example of this. Inseparable from this group, unless examination of a previous illness has been of assistance, will be the group of recurrent myalgias. This group can be divided clinically into those cases which always have myalgic spots and general nodules and those which are quite free during the summer but fairly regularly develop an attack during the winter. The first of these subgroups is generally regarded as having a toxic-infective basis, and may contain some of Copeman's cases associated with an incompletely resolved infection. The second appears to contain idiopathic cases of unknown origin. If nearly everyone has had an acute illness of an influenzal type during his lifetime, without further investigation it is not possible to say how many of them fall into Copeman's group. It is likely, however, that some of his cases fall into both of these two subgroups, and that owing to his observations they may now be picked out, making the reservation that there is in these cases some additional anomaly which is not present in those cases which recover after their acute infection.

The third group is metabolic in origin; good examples are gout and diabetes.

The last group comprises local manifestations in muscle and fibrous tissue. These cases are usually associated with trauma and local stress and strain, as in osteo-arthritis of the hips and the so-called periarticular fibrositis, most often seen in infective (rheumatoid) arthritis but not confined to that disease.

The question of the radiation of pain from these myalgic areas appears to be more a matter of the anatomical location of the lesion than of its nature.

In a day when extensive laboratory and biochemical investigations are considered an essential preliminary to any contributory

to medical knowledge it is pleasant to see that a physician in the field can by care and accurate observation still make a substantial addition to our knowledge of medicine.—I am, etc.,

London, W.I.

ERNEST FLETCHER.

Treatment of Lupus Vulgaris

SIR.—Your annotation on the treatment of lupus vulgaris (Sept. 18, p. 366) is very timely, and prompts me to comment on what you no doubt are correct in labelling "a national disgrace."

The City of Liverpool can claim exemption from this stigma. Some ten years ago, as dermatologist to the Liverpool Corporation hospitals, I felt that the disease was being treated very haphazardly by out-of-date methods and with miserable results. During a "bus-man's holiday" I visited many skin hospitals in London, and eventually arrived at the London Hospital, where I was given every facility by Dr. O'Donovan. He personally showed me the lupus clinic referred to in the annotation. I gave a verbal account of my experiences and embryo recommendations to our M.O.H., Dr. W. M. Frazer, and his deputy, Dr. C. O. Stallybrass, and they urged me to draw up a detailed report which they would bring to the notice of the City Council. This was done, and I was sent to the London Hospital again, where with the active help of Dr. O'Donovan and his sister-in-charge I learnt all the details. I tried to keep the expense of the proposed clinic in Liverpool to the lowest limits, but the Liverpool City Council insisted that no reasonable adjunct to the successful treatment of lupus should be spared. The result is that there has been in Liverpool for the past nine years a lupus clinic which will bear comparison with any in this country. We were especially fortunate in securing the services of a sister who had been trained by a nurse from the Finsen Institute in Copenhagen. Our Finsen-Lomholtz lamps do not require the whole-time attention of a nurse; with the active co-operation of our electrician they have been made foolproof and entirely automatic when once the patient has been placed in the required position; in fact all our water-cooled lamps have an ingenious arrangement whereby a failure in the water supply immediately cuts off the current, and any movement by the patient whilst under treatment by the Finsen lamp immediately rings a bell and brings a reprimand from the charge nurse.

The results of the treatment, particularly in the early cases, were so excellent that I conducted research in the haematology of the disease during treatment. These results were to be embodied in a chapter of a textbook on lupus edited by Dr. Airey in conjunction with other workers in special fields, but publication has had to be postponed till after the war. Dr. Airey paid a visit to the clinic, and appeared to be very impressed with it: in fact I like to think that his remarks in the *Bulletin of the National Association for the Prevention of Tuberculosis*, to which you refer, had some part, at any rate, of their inspiration from his visit to the City of Liverpool Lupus Clinic at Belmont Emergency Hospital. Although we have not the help of ancillary specialists in the building, nevertheless there is complete access to such help in the service of the Corporation, and it has been freely given.

It should be said that the vast majority of cases have been either cured or sufficiently relieved to perform useful work. As your annotator points out, the treatment is long and expensive, but its success in the absence of active lesions in the chest (11% in our cases) is so probable that it is well worth while. Local authorities in the surrounding areas have made use of the clinic, and it can be said that in this field the Liverpool authorities have shown that they are ready to support the suggestions of their medical advisers when the need is fully explained to them.—I am, etc.,

Liverpool.

F. GLYN-HUGHES.

SIR.—Under the above heading (Sept. 18, p. 366) I find this remark: "The fact that the disease is not treated with all the means which modern science has put at our disposal is a national disgrace. Probably the chief reason for this deplorable state of affairs is financial. Lupus vulgaris is one of the most expensive diseases there is to treat." About twenty years ago the late Drs. Stophord Taylor and McKenna placed cases at my disposal for treatment at the Liverpool Skin Hospital. At the end of three months the worst and most

extensive case was healed up; the patient had been attending the hospital for nine years. Dr. McKenna remarked: "I confess I was an absolute sceptic until I saw your work, but results speak for themselves." He then said: "You must have been considerably out of pocket for tuberculin." I replied: "I had used eighteen pennyworth of P.T.O. for the dozen or so cases treated."

Why will not the scribes and pharisees and high priests of the medical profession condescend to learn the technique for the correct use of such an efficient and cheap remedy? But I suppose it has been ever thus.—I am, etc.,

West Kirby.

ADAM MOSS.

Toxicity of Methyl Acetamide

SIR.—The leading article on stimulation of leucopoiesis (Sept. 18, p. 365) suggests that the work of Zondek and Bromberg on the evocation of leucocytosis by 25% *p*-chloroxylenol in methyl acetamide is worthy of attention. The writer has ignored the evidence of the great toxicity of methyl acetamide. Kuhn (*Chemical Abstracts*, 32, 4200) called attention to the grave and sometimes fatal effects of this substance in small doses in rats; and Weslaw *et al.* (*Chemical Abstracts*, 32, 8580) confirm this. In the fear that somebody will lightly use 50 c.c.m. of this substance over a period of three days I call your attention to the need for warning the readers of the leading article.

Incidentally, it would be interesting to learn what evidence there is for supposing that pentose nucleotides cause only redistribution and mobilization of preformed leucocytes.—I am, etc.,

London, W.I.

A. PNEY.

Precision Method of Cephalometry and Pelvimetry

SIR.—Dr. Paul Cave (Sept. 18, p. 375) has replied to my criticism of his article on cephalometry and pelvimetry with such patience and competence that it is ungracious not to be satisfied, but I would be grateful for the opportunity of making some final comments on the subject.

The claims originally made for the application of his method in depth localization generally are abandoned in the reply, I am glad to note, and the only merits claimed are in the field of obstetrics. So far as the technical side is concerned, the original article described a tube-shift in the vertical direction from 30 to 60 in., which is modified in the reply to a shift from 30 to 40 in., and this avoids several of my criticisms, but, of course, also reduces the image-shift and makes accurate measurement more difficult. The actual error introduced with these new distances is, as Dr. Cave calculates, only a small fraction of an inch, which is probably not at all serious by itself, but it is surely unwise to advise the use of a method that starts off with even a small inherent error, which is certain to become multiplied by slight inaccuracies in technique and calculation, when other methods are not so handicapped and are, in theory at least, exact.

Comparison of the vertical and lateral tube-shifts does not uphold his claims; calculations may be made of pelvic or foetal measurements by a single formula in either case, and a lateral tube-shift can usually be made with very great accuracy, as most x-ray plants are provided with a slide clamp on the tube stand to enable a definite shift to be made without making measurements or scale readings, which are, of course, needed in a vertical shift. His example of the disastrous effects of an error of some inches in a lateral shift is misleading, as the only possible error in moving the tube between fixed stops would be a minute fraction of an inch, while the accuracy of vertical movements depends on personal observation of scale marks, with the possibility of errors from parallax and obliquity as well as from human failings. Actually, with a lateral tube-shift, it is not necessary to know the tube-film distance, as the calculation in pelvimetry is one of simple proportion involving horizontal distances only.

I am sorry to impose on your space further, but I believe that the science of radiology should not be encumbered with doubtful methods of producing results which can be achieved by well-tried and accurate procedures, and I consider that in this case nothing is to be gained by advocating any departure from orthodox practice.—I am, etc.,

Hove.

E. MILLINGTON, D.M.R.

Artificial Insemination

SIR.—The correspondence arising from Dr. Mary Barton's letter (Sept. 4, p. 312) has dealt only with the sterile husband. There is another aspect—that of the man whose desire to fulfil his function of fatherhood is thwarted by the infertility of his wife from disease local or general. Advice to adopt a child is not an answer to this problem.

The letter of Dr. Anne McCandless (Oct. 2, p. 414) raises an important question. The position of the professional woman, highly intelligent and physically fit, denied the opportunity of transmitting her abilities to future generations is indeed tragic both for herself and for the State. Whatever method were adopted the Church would no doubt oppose, and be supported by those medical men who so readily state that continence is harmless but never supply any scientific proof of this *ex cathedra* statement.—I am, etc.,
London, W.1.

PEARSE WILLIAMS.

Unity in the Profession

SIR.—Criticism is a healthy sign of interest, but it is unfortunately often ill directed and based upon ignorance. Mr. Donald Watson stated in his letter (Sept. 25, p. 405) that "Dr. Buchan was chosen to serve on the Representative Committee. Do you desire men of his outlook—control and regimentation—to be elected to the Negotiations Committee?" The obvious inference from his letter is that Dr. Buchan was elected by some part of the B.M.A.. If Mr. Watson will take the trouble to look at the *Journal* for March 20 last (p. 359), he will find that Dr. G. F. Buchan was one of the two Representatives of the Society of Medical Officers of Health, and was not chosen by the B.M.A.. He presumably represents the views of the Society of Medical Officers of Health. The Representative Committee is not a committee elected by the B.M.A., though its composition was approved at the Special Representative Meeting held on March 31, 1943. The Royal Colleges, the Society of Medical Officers of Health, and the Medical Women's Federation elected representatives to serve on this committee.

In the medical profession there are many interests—general practitioners, consultants, teachers, women doctors, medical officers of health, the staffs of municipal hospitals, etc. It was thought, and I submit, very wisely thought, by the Council of the B.M.A. that for a satisfactory solution of the immediate problem of planning a comprehensive medical service, or considering any Government plan, it would be better that all the varied sections of the profession should get together and present a united front. There was a movement by the Royal Colleges to represent the consultants, but they gave way for the common good and agreed to work through the Representative Committee. Many consultants feel that the Colleges might have looked after their particular interests better, but in doing this the general practitioners might have been let down. Similarly, the medical officers of health have been let down. Health, and might from a sectional point of view have done better by playing their own game. Had this anarchy in the profession developed the Government, in face of a divided profession, could have made what plans it wished with no effective opposition.

Mr. Watson will therefore find various sections and even conflicting views represented on the Representative Committee. Not a certain amount of give and take is required. We shall not oppose whole-time salaried M.O.H.s. and they presumably will let the G.P.s settle what they want: in any case the M.O.H.s. form a small minority. Dr. Buchan has proved of outstanding service to the Representative Committee: his knowledge of central administration and his exposure of the confusion and overlapping in the various Government Departments have been of inestimable benefit. It is to be hoped that in future criticism of the Representative Committee the critics will at least have troubled to study its composition and method of formation. It is, of course, open to any member to criticize the Council for joining this team instead of taking part in a "free-for-all" scramble, but I feel that on consideration Mr. Watson would not approve of the latter course.—I am, etc.,
H. J. McCURRICHI.

H. J. McCURRICHI.

Medicine under State Control

SIR.—Dr. J. N. P. Davies's letter (April 17, p. 490) dealing with the relationship of the patient with the State in any comprehensive health service has been read with great interest and relief by a small number of Service doctors stationed far away and therefore unable to follow events at home as soon as they would wish.

It does seem that many of us who have now had four years' experience of Service medicine, and not from the viewpoint of the regular Service medical officer, are now well qualified to submit our views on the very important aspect of the patient's point of view of Service medicine, which, after all, is closely parallel to any comprehensive health service for civilians after the war. For instance, the methods available in the Services for the detection and prevention of those "socially dangerous diseases" which Dr. Davies cites are only one example of the fundamental difference between Service medicine and the ordinary system of voluntary organization for the treatment of disease.

It follows, as Dr. Davies so clearly points out, that an reorganization of the medical profession and the health service will affect the great democratic public. Are they, the patients, aware of the sense of freedom they are going to lose? The possible penalties they may incur if they refuse treatment? The certain loss of a portion of their cherished right and privilege of professional secrecy, when the doctor has his "quarterly returns" to fill in? The criminal view that must be taken by the State of neglect and failure to carry out treatment calculated to restore the patient to health in the shortest possible time in order that he may return to work? And also the slightly lowered prestige of the family doctor if he becomes completely a servant of the State, thereby losing some of his independence, which has been treasured in the past as much by his patients as by the doctor himself? Let the legislators take care that they, and the vast number of individuals they represent, are aware of all the implications that the phrase "comprehensive health service" means.

Finally, as a practical suggestion, would it not be possible to co-opt on the Representative Committee two members from each of the three Services, chosen from officers who have served abroad and are at present stationed at home and likely to remain there for the next year? Apart from their own views they would come with those of their present patients—the men and women in the Services—who have their ideas about a State Medical Service.—I am, etc.,
J. B. W. HAYWARD, M.B., Ch.B.

The Classics in Medical Education

SIR.—It is a truism to say that both the medical and pre-medical curricula are overcrowded. Even so, I feel sure there are many doctors (and I am of their number) who echo Dr. Clark-Kennedy's plea for the incorporation (through the study of English translations) of the historical and philosophic content of the classics. On the other hand, I doubt if many are anxious to do it by making compulsory the study of Latin itself.

The immediate difficulty is that for the schoolboy on the modern side such Latin literary masterpieces as form his studies are not employed for this purpose at all, but are used as a method of learning Latin grammar. As one scholar has it: "The Commentaries usually serve not as military history, but as a whetstone for gerund grinders." This, no doubt, is a good way of learning Latin, but is a slow and poor way of learning how the Romans thought and acted. About six years of study has left me to-day with the ability to translate the less idiomatic Latin quotations found in scientific papers—which, by conversations on this point with them, is not below the average of my medical contemporaries. When I have protested to schoolmasters in conversation that for a surgeon this is rather slight return for six years' reasonably assiduous work at a formative period, I am usually met with the following arguments:

1. That, being difficult to acquire, "Latin is mental discipline." The best answer to this is the remark of a bored schoolmaster at a Head Masters' Conference: "It doesn't matter what you teach a boy so long as he doesn't like it." Dr. Norwood at Harrow, following this thesis, made German an alternative to Latin.

2. "Latin is a guide to the etymology of scientific terms." As learnt more of the etymology of anatomical terms in ten minutes' study of the glossary in Buchanan's *Anatomy* than in six years' Latin schooling, I find this argument unconvincing.

In 1641 John Amos Comenius, the Czech educational reformer, visited England and revolutionized the lot of schoolchildren by insisting that they be taught not in Latin but in the mother tongue. Is there any hope that in this generation the process may be brought to its logical conclusion, and that of scientific occupations the content rather than the language of the classics be taught? I doubt it.

The trouble is that too many schoolmasters can still teach nothing else, and that for them a knowledge of the language of the classics and sound scholarship are synonymous. Their position is that of Dr. Arnold of Rugby, so aptly described by Lytton Strachey:

"Dr. Arnold felt that the Greek and Latin languages seemed even for the purpose of forming the human mind in youth . . . there was something providential about this, both from the point of view of the teacher as well as the taught. If Greek and Latin had not been 'given' in that convenient manner Dr. Arnold, who had spent his life in acquiring these languages, might have despaired that he had acquired them in vain."

—I am, etc.,

Leeds.

JOHN FOSTER.

Obituary

E. N. NASON, M.D.

We regret to record the death on Sept. 18 at Nuneaton of Dr. E. N. Nason, a well-known practitioner in the Birmingham district, and for a number of years a member of the Council of the B.M.A.

Edward Noel Nason, son of Dr. Richard Nason of Nuneaton, was born in 1862. He was educated at Shrewsbury School and won a scholarship at Downing College, Cambridge. After obtaining his B.A. degree with honours in 1885, he completed his clinical studies at the London Hospital and took the Conjoint Diploma in 1886, subsequently proceeding to the Cambridge M.B. in 1887 and M.D. in 1897. After acting as house-surgeon at the London Hospital and at the Norfolk and Norwich Hospital, he was appointed resident surgeon at the General Hospital, Birmingham. Though equipped by nature and training to embark on the career of a consulting surgeon, it was ordained that he should join his father and younger brother in the family practice. The name of Nason thus became associated with a practice in Nuneaton for nearly one hundred years. On embarking in practice Nason was not content until he succeeded in obtaining a hospital to serve the needs of the populous industrial district in which he practised. He became the mainspring in the work of the hospital, and from small beginnings lived to see the institution he had fathered steadily grow into a prosperous and well-equipped hospital of over a hundred beds, complete with nurses' home and maternity wing. For many years he continued to carry out the bulk of the surgical work himself, and was a tower of strength in all matters connected with the administration and running of the establishment. Always a keen man in any matter affecting the profession, he was in turn president of the Birmingham Branch and for two periods a member of the Council of the B.M.A. He rarely missed a meeting either in Birmingham or of his own Nuneaton and Tamworth Division. He also took a keen interest in all local affairs, particularly in their bearing on the public's health, and was for a time a member of the Warwickshire County Council. He leaves a widow and two sons—one of whom is serving as a chaplain in the Royal Navy, the other in the Army—and two daughters.

As a former colleague I would like to add a few words of personal tribute to a man who served his profession and the neighbourhood in which he lived so faithfully and so well. Nason was a man of strong convictions, and he would never allow his own self-interest to swerve him from a course he considered to be right. Thus, a strong opponent of the National Health Insurance Act at its inception, he and his brother refused for many years to join the panel, even though the financial benefit to be derived from doing so would have been considerable. He held very high ideals of professional conduct and abhorred above all else the commercializing of the profession. Of a naturally reserved disposition, he possessed a quiet but keen sense of humour, and was one of the kindest men one could meet. He was always ready to help a colleague either with a difficult case or with advice in the knotty problems which arise in practice, and such advice he was particularly well equipped to give; of a deeply sympathetic nature it was yet entirely foreign

to him at any time to be gushing. He was never happier than when he was in the garden he loved and tended so well. I have vivid recollections on many occasions of seeking him out there and not seeing him at first, finally discovering him hidden in one of his apple trees busy with the pruning knife. He thoroughly enjoyed a day out with gun or rod. He was a staunch churchman, and served for years as churchwarden of St. Mary's, close to his home. His knowledge in professional matters was profound, and he kept it up to date by diligent reading of the *B.M.J.* He was always surprising one by the depth of his knowledge of pathology.

Nason was a doctor of the very best type, one of those who by the example of his own daily life wielded an unconscious influence over those around him. If the apprenticeship system should ever return, one could wish for nothing better than that the embryonic practitioner should serve his term with a man such as he.

C. J. G. T.

RALPH BODKIN MAHON, M.D., M.Ch., F.R.C.S.

With the death of Emeritus Professor R. B. Mahon there has passed an outstanding figure from the medical profession in Galway, who for a long period took an active part in the local and central work of the British Medical Association in Connaught, in Dublin, and in London.

Ralph Bodkin Mahon, son of Nicholas Mahon, a Galway practitioner, was born in April, 1862, and had a brilliant student career in Galway and Dublin. In 1885 he graduated M.D. and M.Ch. of the old Royal University of Ireland, with first place in the first-class honours list, after winning a junior scholarship and an exhibition at Queen's College, Galway, and a senior scholarship in anatomy and physiology. He continued his studies in London, Berlin, Munich, and Berne, and on returning to Ireland became demonstrator of and assistant lecturer on anatomy at Queen's College, Galway, and then demonstrator of anatomy and assistant to the professor of physiology at Queen's College, Cork. In 1896 he obtained the F.R.C.S. Eng., and after holding a clinical post at the Eye, Ear, and Throat Hospital at Cork went back to Galway, where he was elected visiting surgeon to the Central Hospital. Some time later he succeeded to the chair of the practice of medicine at University College, Galway, which had become in 1903 a constituent college of the National University of Ireland. He held a temporary commission in the R.A.M.C. during the last war as surgical specialist to the Southern Military Hospital, Darford.

Prof. Mahon joined the B.M.A. 54 years ago, and his colleagues made him president of the Connaught Branch in 1923-4; he served for three periods (five years in all) on the Central Council, and was a member of the Irish Committee of the Association in 1923-5. He wrote a number of papers for the *British Medical Journal*, and kept up his acquaintance with professional life in London and Dublin by remaining a Fellow of the Royal Society of Medicine and of the Royal Academy of Medicine in Ireland. He had travelled widely in South America, Canada, the United States, and Norway, and was devoted to shooting, fishing, and golf.

Dr. HAROLD ERNEST GAMLEN died towards the end of July at North Cheriton, near Templecombe, Somerset, at the age of 72. He studied medicine at Newcastle-upon-Tyne and won the Gibb Scholarship in Pathology in 1892; in the following year he graduated M.B., B.S. of Durham University and took the D.P.H. in 1895. Dr. Gamlen specialized in x-ray work and was for many years radiologist to the Sunderland Royal Infirmary and physician to the x-ray, electrical, and massage departments of the Royal Victoria Infirmary, Newcastle. He was also roentgen surgeon to the Cameron Hospital and the Hartlepool Hospital. During the last war he served with the rank of major, R.A.M.C., at No. 11 General Hospital, B.E.F., and was consulting radiologist to the Indian Expeditionary Force. On retiring from practice he made his home at North Cheriton.

Dr. JAMES MURDOCH MCGILL died on Aug. 23 at the age of 78 at Bonnyrigg, Midlothian. His father, Dr. John Finlay McGill, was a general practitioner at Coylton, Ayrshire, and between them father and son for nearly a hundred years attended to the medical needs of the people of Coylton, Stair, and Annbank. After education at the Ayr Academy and at Edinburgh University James McGill graduated M.A. in 1885 and M.B. in 1889, and practised in his native town until 1931. When he gave up active work Dr. McGill had a public presentation contributed to by over 800 homes in the parish and far beyond; this testified to the respect and esteem in which he was held in the neighbourhood. The Right Hon. James Brown, in making the presentation, said that Dr. McGill was their neigh-

bour and their friend in every sense of the word, and everyone present would like him to know how much they respected and loved him and how much they grieved at the parting.

Dr. FRANCIS DIXON, who had practised at Eastwood, Notts, for nearly half a century, died recently in his 88th year. Born at Langley in 1855 he studied medicine in Edinburgh and Glasgow, and qualified as L.R.C.P., L.R.C.S.Ed. in 1878, and took the L.S.A. a year later. Dr. Dixon was medical officer of health to the Eastwood Urban District Council for many years up to the time of his retirement from active work in 1926. A fine all-round cricketer in his younger days, he was invited to serve on the committee of the Notts County C.C., and did good work in that capacity for over 40 years. He joined the British Medical Association as long ago as 1882.

We regret to announce the death on Aug. 28 of Mr. GEORGE AUBREY JELLY, who practised as an ophthalmologist at Lytham, Lancs, for many years. Born at Middleton, Lancs, on July 2, 1872, son of the Rev. James Jelly, he studied medicine at Edinburgh and Manchester and qualified in 1894, after which he served as house-surgeon at the Royal Eye Hospital, Southwark. He took the F.R.C.S.Ed. in 1899, and was for some time assistant surgeon at the British Ophthalmic Hospital, Jerusalem. Returning to this country he was appointed honorary ophthalmic surgeon to the Bury Infirmary and to St. John's Hospital for Diseases of the Ear and Eye in Manchester. During the last war Aubrey Jelly served with the rank of temporary captain in the R.A.M.C. as ophthalmic surgeon to the 3rd Western General Hospital, Cardiff; later he became oculist to the Cheshire County Council. He joined the B.M.A. in 1902 and held office as chairman of the Blackpool Division in 1927-8.

News has reached this country from America of the death of Mr. CLIFFORD WHITTINGHAM BEERS, whose name is well known as that of a reformer in regard to the treatment of the insane, not only in the United States but all over the world. Clifford Beers had liaison with over 50 countries through the association he formed in the U.S.A.—the National Committee for Mental Hygiene. An ex-patient himself, he wrote in 1907 the book *A Mind that Found Itself*, which has gone through many editions and reprintings. Through this autobiography and by other means he enlisted the interest and help of many distinguished people, medical and other, in supporting the work of his society, notably Prof. William James in America and Sir Maurice Craig in England. William James wrote to the author: "You have handled a difficult theme with great skill and produced a narrative of absorbing interest to the scientist as well as layman. It reads like fiction, but it is not fiction . . ." *A Mind that Found Itself* is indeed a remarkable book and its effect has been far-reaching; it made a profound impression upon the medical profession as well as upon the general public. Its logical outcome was the founding of the National Committee for Mental Hygiene in 1909 and the establishment in 1917 of the quarterly journal *Mental Hygiene*. The movement spread from the United States to Canada and to Europe. In this country Sir Maurice Craig was a founder of the National Council for Mental Hygiene, which is now forming part of the Provisional Council for Mental Health, with a view to possible further amalgamation after the war with the Child Guidance Council and the Central Association for Mental Welfare.

Universities and Colleges

UNIVERSITY OF SHEFFIELD

following candidates have been approved at the examinations stated:

—R. B. Knowles
M.B., Ch.B.—Parts II and III. J. W. Greaves, A. Pickin, Winifred M.

UNIVERSITY OF ABERDEEN

a graduation ceremony on Sept. 29 the following medical degrees were conferred:

M.B., Ch.B.—I. W. Burnett, R. N. Johnstone, M. R. Milne, J. R. Anderson, R. J. Anderson, E. C. Baird, Sheila M. Baker, J. B. Bittner, H. Brebner, G. W. D. Campbell, Mary E. Chalmers, G. C. Chessor, C. Clark, Catherine M. Coull, I. C. Cowan, M. M. Craig, Thelma C. Cruickshank, Sheila R. Dalrymple, W. J. Dawson, R. C. MacD. Dingwall, G. A. Findlay, D. A. Forbes, A. G. Fraser, I. A. The Services.

CASUALTIES IN THE MEDICAL SERVICES

Surg. Lieut. W. L. MACKENZIE KING, R.C.N.V.R., nephew of the Canadian Prime Minister, is stated by Reuter to be one of the nine officers missing from the *St. Croix*.

Missing, believed killed at sea.—Lieut.-Col. H. Foxton, M.C., R.A.M.C., Major C. Ryan, R.A.M.C.

Missing, presumed killed.—Prob. Temp. Surg. Lieut. C. M. Davies, R.N.V.R., Temp. Surg. Lieut. G. C. Glennie, R.N.V.R.

Died on Active Service.—Major R. S. Gibson, M.C., R.A.M.C.

Killed.—Capt. L. Herbert, R.A.M.C.

Previously reported missing, now presumed killed in action.—Capt. H. B. Thomson, R.A.M.C.

Prisoners of War.—Lieut.-Col. J. C. Collins, R.A.M.C., Surg. Lieut. J. P. Corcoran, R.N., War Subs. Capt. J. A. Mark, E. H. Markby, T. B. Smiley, and R. B. Wallace, D.S.O., M.C., and Lieut. E. C. Vardy, R.A.M.C.

Medical Notes in Parliament

Mass Radiography

Mr. BROWN, replying on Sept. 23 to Mr. Ness Edwards, said he was not aware of any substantial disagreement with the recommendation of the M.R.C. Committee on Tuberculosis in Wartime, which reported in September last year in favour of the controlled use of mass radiography as a means of detecting tuberculosis at an earlier and more controllable stage of the disease. It had never been suggested that mass radiography could replace clinical examination: its function was to indicate the cases in which clinical examination was desirable.

Alien Doctors and Dentists

Mr. BEVIN stated on Sept. 23 that from a detailed scrutiny of the registration cards of 5,000 German and Austrian men in this country it was found that a large proportion with high professional and technical qualifications were employed in their normal occupations. Of 184 physicians and surgeons all but 9 were employed in the medical profession; of 55 dentists all but 2 were employed as dentists; all dental mechanics were engaged in their trade.

Local Authorities' Powers of Milk Inspection

Mr. KENDALL asked the Minister of Health on Sept. 23 if it was intended that powers for safeguarding the quality of milk at present vested in local authorities should be transferred to the Minister of Agriculture. Mr. ERNEST BROWN replied that the scope of the powers proposed in the recent White Paper to be transferred to the Minister of Agriculture was at present the subject of discussions. The object was to make the Minister of Agriculture responsible for conditions under which milk was produced at the farm, but the existing powers of local authorities in respect of milk infected with disease or adulterated milk would not be affected.

Slum Conditions in Industrial Premises.—On Sept. 21 Miss HORSBRUGH informed Mr. Craven-Elis that the Ministry of Health had no up-to-date records of the extent of slum conditions in commercial buildings, warehouses, works, and factories. The conditions in buildings of the type mentioned were not the responsibility of the Ministry of Health. Under Section 25 (1) of the Housing Act, 1936, however, a local authority might include in a clearance area buildings other than houses which, for the same reasons as justified the condemnation of the houses, were dangerous or injurious to the health of the inhabitants of the area.

Sun-ray Lamps in Factories.—On Sept. 21 Mr. HANNAH asked the Minister of Health why some firms and not others were permitted to purchase sun-ray lamps for the benefit of their workers employed on night shifts, although medical men urged their use in all cases where they could be employed, and the Ministry of Labour was insisting on the maximum effort for welfare work. Miss HORSBRUGH replied that the Ministry of Health acted as adviser to the Board of Trade on applications by factories for licence to acquire sun-ray lamps. In respect of certain types of apparatus the Ministry's medical advisers had to consider whether adequate medical and nursing staff were available at the premises to ensure that treatment was given under proper supervision. If these conditions were fulfilled it was usual to recommend approval to acquire the apparatus provided alternative facilities for the treatment were not readily available.

Inoculation in the Services.—Answering Mr. Leach on Sept. 22, Mr. CHURCHILL said inoculation was voluntary in all three Services and this was well known. In the Navy, however, in the interests of the health of ships' companies it was necessary to refuse to those who had not been inoculated permission to land in ports where there might be danger of contracting any of the diseases against which this treatment was aimed.

No. 38

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 25.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Includes paratyphoid A and B.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the trend of the infectious diseases of childhood remained unchanged. Notifications of scarlet fever and diphtheria rose by 133 and 34, and those of whooping-cough and measles fell by 51 and 25 respectively.

The only noteworthy local variations were an increase of scarlet fever in Lancashire by 40, and a fall in whooping-cough in Yorks West Riding by 50 cases.

The notifications of dysentery were 2 more than the high level of the preceding week. New outbreaks occurred in Wiltshire, Swindon M.B. 20, and in Norfolk, St. Faith and Aylsham R.D. 12. Only one case was recorded in Cumberland, compared with 54 in the preceding week. The largest of the existing centres of infection were: London 42; Kent 36; Gravesend M.B. 10, Rochester M.B. 16; Devonshire 16, Exeter M.B. 16; Gloucestershire 16, Bristol M.B. 15; Yorks West Riding 16, Harrogate M.B. 10; Lancashire 15; Middlesex 14; Hertfordshire 14; Warwickshire 9.

In Scotland a fall was recorded in the incidence of most infectious diseases. The largest decreases were for whooping-cough 54, pneumonia 32, and dysentery 17 cases.

In Eire the rise in diphtheria was general throughout the country. Of the 140 cases of diarrhoea and enteritis, 127 were recorded in Dublin C.B.

Quarterly Returns for England and Wales

The birth rate during the second quarter of 1943 was 17.5, compared with an average for the five preceding second quarters of 15.7, and the rate was the highest recorded in any June quarter since 1926. Infant mortality was 46 per 1,000 live births, the lowest rate ever recorded for a second quarter, and it was 9 below the average of the 10 preceding June quarters. Stillbirths were 3.0% of the total births registered. The general death rate was 11.0 per 1,000, compared with 11.3 for the second quarter of 1942, and 12.0 for the average of five years before 1942. The natural increase, excess of births over deaths, was 67,457, compared with 50,685, 7,228, and 46,980 for the second quarters of the three preceding years. Persons who married numbered 37,610 fewer than during the June quarter of 1942, and 38,668 fewer than the average for the five second quarters before 1942. The marriage rate, 15.9 per 1,000, is lower than that in the second quarters of the years preceding the war.

Quarterly Returns for Northern Ireland

A birth rate of 26.7 per 1,000 was recorded during the second quarter of 1943. This rate was 4.4 above the average for the second quarters of the five years 1938-42. Infant mortality was 74 per 1,000 registered births, and was 2 above the five-year average. The general death rate was 13.3, and was 1.1 below the average of the five preceding second quarters. Of deaths of children under 2 years, 105 were attributed to diarrhoea and enteritis, compared with the five-year average of 70. Deaths from pulmonary tuberculosis numbered 220 and from other forms 92, the former being 21 below the average of the June quarters of 1938-42, while the latter was 14 above. The marriage rate was 8.1 per 1,000; this was 1.8 below the rate for the corresponding quarter of 1942, but 0.3 above the average of the second quarters for 1938-42.

The Week Ending October 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,956, whooping-cough 1,583, diphtheria 724, measles 465, acute pneumonia 407, cerebrospinal fever 30, dysentery 337, paratyphoid 7, typhoid 7.

Daube (*Klin. Wschr.*, 1942, 21, 679) describes four cases of "pervin psychoses" observed at the Hamburg Psychiatric Clinic. In the first case it seems that ambition and increased demands on the capacity of the addict, together with general asthenia, provoked the choice of pervin. The second patient was attracted mainly by the euphoric action of the drug. In the third physical injuries and strains (severe x-ray burns, amputations, plastic operations) were the main factors; and in the fourth case abnormal tendencies were already present in the direction of a hyperthymic impulsiveness, affective unbalance, and increased "impatience drive." Besides the increased physical efficiency hoped for from the drug, it was also used as a sexual stimulant. None of the four cases had any previous history of psychosis, and in none of the cases could a hereditary defect be ascertained. Addiction developed very rapidly. The psychotic disturbances themselves showed many common features. At first there developed a pronounced anxiety state occasionally coloured by irritability. Combined with this a wealth of assertive and paranoid ideas were expressed with illusions and hallucinations. The psychosis disappeared fairly

Medical News

The Royal Sanitary Institute has arranged a sessional meeting in the Pump Room, Bath, on Saturday, Nov. 6, at 10.15 a.m., when there will be discussions on food standards and on the post-war housing problem.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital, St. George's Circus, Southwark, S.E., on Friday, Nov. 5, at 4.30 p.m., when a talk will be given by Mr. Harvey Jackson, F.R.C.S., on orbital tumours.

The British Institute of Philosophy announces a lecture entitled "Community Purpose and the Lessons of Nazism," to be delivered at University Hall, 14, Gordon Square, W.C.1, on Friday next, Oct. 22, at 4.30 p.m., by Prof. J. W. Harvey of Leeds University. Cards of admission may be had free of charge from the Director of Studies at University Hall.

The Nutrition Society has arranged a whole-day conference on "Post-war Nutritional Relief" at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., on Saturday, Nov. 6. The chair will be taken by Lord Horder, and papers will be read by Prof. J. R. Marrack ("Past Experience and Present Position"), Dr. J. Hammond, F.R.S. ("Problems of Production in Relation to Post-war Nutritional Relief"), Miss E. M. M. Hume ("Opportunities for Nutritional Research in the Work of Relief"), and others. Further details of this meeting, and of the Nutrition Society, can be obtained from the hon. secretary, Dr. Leslie J. Harris, Nutritional Laboratory, Milton Road, Cambridge.

A conference on Mental Health will be held in Caxton Hall, Westminster, on Friday, Oct. 29, under the auspices of the Provisional National Council for Mental Health (39, Queen Anne Street, W.1). The conference will be opened at 10.30 a.m. by the Minister of Health, and at the morning session Sir Otto Niemeyer will speak on the development and extension of voluntary mental health services, Dr. Thomas Beaton and Mr. E. R. Davies on mental health work of local authorities, and Mr. J. Duncan on the residential school and its place in the education of defective and subnormal children. At the afternoon session, with Sir Farquhar Buzzard in the chair, Dr. J. S. I. Skottowe will speak on the effect of war conditions on the mental health of the community, and Miss L. G. Fildes, Ph.D., on selection and classification of homes and hostels in relation to the needs of the individual child.

The Socialist Medical Association will hold a conference on National Service for Health on Sunday, Oct. 17, at 3 p.m., in the Conway Hall, Red Lion Square, W.C., with Dr. H. Joules in the chair. The speakers are Mr. Hector McNeil, M.P., and Mr. Somerville Hastings, F.R.C.S.

The North Kent Section of the British Dental Association will hold a meeting at the Star Hotel, Maidstone, on Friday, Oct. 29, at 6.45 p.m., when Dr. Wilfred Fish will speak on the mechanism of systemic response to infected foci.

Through the generosity of some leading firms in the country a medical rehabilitation centre is being established in Sussex, at Roffey Park, Horsham, with accommodation for 120 patients. The Ministry of Labour and other Government Departments are collaborating, and the chairman of the organizing committee is Lord Horder. Among the functions of the centre will be instruction in industrial health for doctors, social workers, and nurses; and facilities will be provided for research on social and industrial medicine.

The British War Relief Society of the United States has decided to give £30,000 to the Queen Victoria Cottage Hospital, East Sussex, which specializes in plastic facial surgery. The gift will be a memorial of the society's work in this country during the last four years. In 1942 alone the society shipped to Britain 7,900 tons of material, and it has given 312 ambulances and motor vehicles and 1,000 mobile kitchens; it also equipped the American hospital at Oxford.

The Insignia of the Fourth Class of the Order of El Istiqlal has been conferred upon Dr. S. A. Jones, medical officer in the Arab Legion, in recognition of valuable services rendered by him.

Dr E. A. Knappett has been commended for brave conduct when an aircraft crashed and caught fire.

A Swiss Society of Psychology has recently been founded on the initiative of Prof. Piaget of Geneva, Prof. C. G. Jung of Einsiedeln, Dr. O. Forel of Prangins, and Dr. Morgenthaler of Muris.

Institute for typhus research, named after Emil von Behring, has been opened at Lemberg, and a special typhus institute in Dresden for the wholesale preparation of typhus

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Kraurosis Vulvae

Q.—In some recent correspondence about the use of oestrogens it has been stated that the dosage should not exceed 1 mg. Cases of menopausal kraurosis vulvae appear to need much larger doses for their resolution, and still more so the case occurring in a younger woman after oophorectomy. Could you give some guidance on this point?

A.—In the course of the correspondence referred to it is stated (*Journal* p. 244) that "symptoms in women of menopausal age which do not respond to less than 1 mg.—other than such late sequelae as atrophic vaginitis—are not due to ovarian deficiency." A considerable portion of the letter in question was devoted to pointing out that the threshold of sensitivity to oestrogen varies greatly at different phases of the female life span. During the "menopausal age," when the woman is actually undergoing gradual oestrogen deprivation, she is relatively sensitive to oestrogen, and therefore quite small doses (i.e., less than 0.5 mg.) are effective in relieving hot flushes, etc. Kraurosis vulvae is a post-menopausal condition resulting from relatively long-continued oestrogen deprivation and therefore requires higher dosage. The severity of the condition depends primarily on the length of time the tissues have been deprived of oestrogen and not on whether the menopause was physiological or resulting from surgical removal of the ovaries. Dosage depends, of course, on the severity of the condition. A course lasting not longer than 2 months and preferably not more than 3 or 4 weeks of 5 mg. of stilboestrol or natural oestrogen daily usually relieves the kraurosis for a period of a year to eighteen months. An alternate method of administration is to implant a 50-mg. pellet of oestrogen subcutaneously and remove the remnant after 1 to 2 months. Uterine haemorrhage may occur during such high-dosage therapy.

Tuberculosis in Children

Q.—It is stated that pulmonary tuberculosis is rare below the age of 7, although glandular tuberculosis is common. Yet T.B. infection—as determined by the Mantoux test—in children from birth to 5 years is five times greater in children who are contacts with sputum-positive cases than in those who are non-contacts. What tissue or organ does the human type of tubercle bacillus invade in the Mantoux-positive contact child?

A.—Tuberculous infection in the first five years of life is a much more fatal disease than it is in later childhood. Blacklock (M.R.C. Spec. Rep. Ser., No. 172, London, 1932) found that over 95% of children up to 3 years of age in whom tuberculosis was present at necropsy died as a result of that infection. About four-fifths of the fatal cases of tuberculosis in childhood are due to infection with the human type of tubercle bacillus. Intimate child contacts of cases of "open" tuberculosis are most often infected by inhalation. The primary lesion is usually a localized patch of bronchopneumonia (the Ghon focus) with secondary infection of the tracheo-bronchial (hilar) glands. The primary lung lesion does not caseate as a rule, but with advancing age of the child shows instead an increasing tendency to heal, fibrose, and calcify. Other children, particularly at the crawling stage, acquire an abdominal tuberculosis by swallowing infected dust and dirt—the infection de touche à tout of French authors—while others, again, develop surgical tuberculosis—infection of glands, bones, and joints.

About half of these surgical infections are due to the human type of bacillus; they are not, as is too often believed, preponderantly due to the drinking of tuberculous milk. Thus, surviving children infected by intimate contact with cases of open tuberculosis have a variety of tuberculous lesions which may or may not be accompanied by clinical or radiological evidence of infection. The adult type of pulmonary tuberculosis with caseation and cavitation is seldom seen in childhood, because it represents a type of lesion occurring in an individual already "tuberculized."

LETTERS, NOTES, AND ANSWERS

OCT. 16, 1943

Feeling the Cold

Q.—Some people complain that they feel the cold to a much greater degree than does the normal person, although otherwise they appear to be in good general health. Even the wearing of thicker woollen clothing does little to obviate the trouble. This is a very real problem for these people in days of fuel economy, etc. Is there any real treatment for such cases, such as the daily administration of halibut-liver oil? Or must their reaction to cold be considered "normal" for them?

A.—"Feeling the cold" depends upon at least three factors—psychological, vascular, and endocrine. Probably the first is the most important. Many people have been taught from their earliest years to regard being cold as a serious hardship. This is particularly true of well-to-do people brought up in large towns. It is possible to train oneself to neglect all but the most serious degrees of cold.

Although the vascular response to cold has been studied in great detail, very little work has been done on individual differences in reaction. Sir Thomas Lewis has postulated a condition in which the normal peripheral vasoconstriction which occurs when the body is chilled fails to pass off with normal speed. He ascribes chilblains to this cause.

The most important endocrine glands involved are the adrenal medullae and the thyroid. The first reaction to chilling of the body is a discharge of adrenaline and consequent peripheral vasoconstriction. Of more "chronic" importance is the control by the thyroid of the degree of intracellular oxidation, and hence of heat production. The hypothyroid individual feels the cold acutely because his temperature is normally low and is easily made lower. He always has cold hands and feet because his heat-regulating mechanism is attempting to conserve his body heat by cutting off the heat loss from the extremities. He often wears an astonishing amount of clothing and cannot sleep without a hot-water bottle. A case has been recorded of a man who in the height of summer could only travel in a closed and heated car, wearing a heavy overcoat.

Treatment should be conducted along the lines indicated by these facts. The prescription of small doses of thyroid (1 gr. a day, working up gradually and watching for signs of intolerance) works dramatically in genuinely hypothyroid cases. As hypothyroidism may not be clinically obvious, it is worth while trying thyroid provided that the patient can be kept under careful observation while the dose is being determined. Halibut-liver oil is quite useless. Nicotinic acid might be worthy of trial provided that it is borne in mind that the cold feet may be a beneficial reaction to a low blood temperature and that in some circumstances it may be inadvisable to interfere.

Arthritis at Menopause

Q.—A woman at the age of the menopause has painful swelling of the small joints of the hands of a month's duration. She is edentulate, the throat and nose are normal in appearance. She does not suffer from dyspepsia, and the urine is sterile. Her general appearance does not suggest thyroid dysfunction. What is the treatment? What are the prospects of cure?

A.—Fuller details are necessary for a definite opinion in this case, especially the erythrocyte sedimentation rate as an indication of an infective process. It is not stated which of the small joints of the hands are affected. It is a point of importance in diagnosis that infective or rheumatoid arthritis rarely if ever shows itself first in the terminal phalangeal joints, whereas Heberden's nodes, a form of osteo-arthritis, always appear there; the opposite is the case for the proximal joints except the carpal joints of the thumbs. It seems most probable that the condition is one of endocrine origin, and small doses of stilboestrol are often effective in giving relief. Locally, contrast baths for the hands will be found beneficial.

Irritation of Ear in Pregnancy

Q.—A young woman has symptoms of marked irritation in the left ear. She is six months pregnant and has had this condition for the last two months. After syringing a little wax out of the ear, the external auditory meatus was seen to be slightly red and scaly in parts; no discharge of any sort was present; the drum was quite normal in structure apart from slight congestion. Is it possible that gentian violet relieves the irritation temporarily? Is otitis externa? In view of the relief afforded in kraurosis vulvae by oestrogen therapy, I wondered (1) whether there would be any danger in applying an oestrogen ointment to this girl's external auditory meatus; (2) whether, if there is no danger, any improvement is likely to ensue; (3) what type of ointment would be best?

A.—Kraurosis vulvae is essentially an atrophic lesion associated with oestrogen deprivation; oestrogen therapy is therefore reasonable and beneficial. During pregnancy the organism is flooded with oestrogen, and even though a large proportion is in a biologically inactive state, there is certainly no evidence of oestrogen

deficiency. Oestrogens have been used for various skin lesions, both in pregnant and non-pregnant women, but their value is not proven except perhaps in cases of acne at puberty or the menopause, when there may be some oestrogen deficiency. In the case quoted there is little if any scientific basis for oestrogen therapy and a good response is unlikely. In my opinion it would be more satisfactory to approach the case from an aural or dermatological, rather than an endocrinological, standpoint. If, however, the inquirer would like to try an oestrogen ointment, it could not be harmful in any way. Oestrone and oestradiol benzoate ointments are supplied by most of the firms specializing in endocrine products and are available in tubes. A little (e.g., 0.5 g. of ointment) could be rubbed into the previously cleansed affected area once or twice daily.

A Buttock Wound

Q.—I was recently discussing with a colleague what might be the ideal treatment for a rather difficult wound which I encountered. I thought you might be able to give some information in your "Any Questions" section. The wound was made by a small shell-fragment which traversed the buttock from above downwards, about 6 inches long, and about 3 inches deep from the skin in its centre. The entrance and exit wounds were very small, and the wound was recent. Complete excision seemed unjustifiably mutilating, yet anything short of this might lead to a very severe buttock infection.

A.—There seems to be no doubt that the cult of excision of wounds has been too enthusiastically accepted, often to the exclusion of common sense. And so it comes about that sometimes more mutilation is done by excision than could ever have occurred from the wound itself, even if some infection supervened. A gunshot wound, if at all deep, is a very complicated cavity; so that even the most extensive excision may fail to remove all devitalized tissues, some of which move away for considerable distances by retraction of contractile and elastic structures and by change in posture after infliction of the wound. Thus the theoretical ideal is not achieved, while extra damage may have been done to important structures in the attempt. This criticism is substantiated by many cases seen in the present war. Further, the local application of the sulphoamides, together with their internal administration, has so affected the question that we feel it is time the whole subject was reviewed. In several cases seen earlier in the war and comparable with that described in the question, a very limited opening of the wounds of entrance and exit, removal of any foreign material, and the instillation of a sulphonamide powder through the track, produced very satisfactory results.

Stilboestrol for Prostatic Cancer

Q.—A patient aged 84 has had his prostate removed. It turned out to be malignant, and he is being treated by deep x-ray therapy. When this course is concluded would it be advisable to put him through a course of stilboestrol? If so, what doses would you recommend, by mouth or intramuscularly, and for how long a period? If intramuscular, would it be preferable to use stilboestrol dipropionate?

A.—There are two ways of proceeding, either scientifically or empirically. If the former course is chosen, the acid serum phosphatase should be estimated, and stilboestrol or hexoestrol given until the acid serum phosphatase is reduced to normal limits. Sufficient dosage should be maintained to keep it to the normal figure. There is no need to give it subcutaneously, as both compounds are completely absorbed through the alimentary tract. Dosage is an empirical matter, starting usually with 1 mg. three times a day and increasing this to 2 to 3 mg. until the acid serum phosphatase is down to the normal figure. As little as 1 mg. a day may control the patient. If there is no access to a laboratory, then 1 mg. three times a day may be increased. The danger of side-effects is very slight indeed, and a large number of cases have been observed which have shown no development whatsoever of side-effects of an unpleasant nature—enlargement of the nipple, etc.

Paget's Disease of Bone

Q.—A male patient aged 65 has been x-rayed, and the diagnosis of Paget's disease of the bones was given. He says very severe pain, especially in the femur and pelvis. (1) What is the prognosis? (2) What treatment can be given? (3) Does aluminium acetate help? If so, what dose should be given? (4) Should the patient be allowed to walk about?

A.—In the examination of many radiographs of patients suffering from other conditions it is frequent to detect Paget's disease of the pelvis and upper end of the femur. The majority of these are without symptoms; therefore one has to be sure that there is not some other condition present responsible for the pain, apart from Paget's disease. One should, of course, be perfectly certain that the radiographic appearances are those of Paget's disease and not, in the case mentioned, secondary deposits of prostatic carcinoma. Where the bones of the hip are involved by true osteitis deformans

the pain is not infrequently due to osteo-arthritis of the hip-joint, the treatment of which is the same as when it is not associated with Paget's disease. Immobilization of the joint for a period is well worth while. In intractable cases operative treatment is occasionally indicated. Before the latter is done, however, there is in the osteo-arthritis associated with Paget's disease a real possibility of relief by radiotherapy. It is by no means certain, but the present writer has seen good results. The rationale of aluminium acetate therapy is not very clear in osteitis deformans. Again this has been used by the present writer and certain of the patients have recorded benefit. The dosage used is that recommended by Helfet (*Brit. J. Surg.*, 1940, 27, 651)—namely, one-third of a drachm given three times a day with syrup and large quantities of milk.

In conclusion, I believe that it is unlikely that the Paget's disease by itself is the whole cause of the patient's symptoms.

A Symptomless Bursa

Q.—Some years ago a patient was diagnosed as having a ruptured internal cartilage of the knee. Two or three years after this, owing to limited movement of the joint through adhesions, the knee was manipulated under anaesthesia and the range of movement restored. There is now, nine years after the manipulation, a fair-sized bursa over the inner tuberosity of the femur. This gives rise to no pain or disability. The patient is not anxious to have an operation, and I should be glad to know if there is any indication for surgical intervention.

A.—It is very difficult to decide from the description given what the exact diagnosis is in this case. However, the commonest bursa on the medial side of the knee-joint is a semimembranous bursa. This is situated postero-medially, and is more prominent with the knee-joint in full extension. The only symptoms it causes as a rule are inconveniences due to its size, or pain due to tension within it. In either of these circumstances an operation should be performed to remove it. In the absence of symptoms, however, as in this case, there is no indication for operation, especially as the patient does not wish it. I cannot see any particular connexion between this bursa and the previous medical history. Both conditions are very common, and therefore quite likely to be coincidental.

The Tobacco Habit

Q.—Is there any drug or chemical which, when administered, gives a distaste for smoking, and, if so, can it safely be given to a smoker? One sees constant advertisements about this in the Press, and I am asked about it from time to time.

Q.—Can any suggestions be offered for the cure of two patients (a male of 55 and a female of 53) who for years have smoked excessively? Both desire to be cured of the habit, but neither has the strength of will to give up the weed. The man smokes a pipe and cigarettes, and the woman cigarettes only. Which is the lesser evil? Could a psychologist help in such cases?

A.—There is no drug or chemical which can be relied upon to give a distaste for smoking. Various preparations which induce nausea may have this effect, and stramonium given in sufficient dosage to cause dryness of the mouth may also act as a deterrent. The most effective method of tackling the problem in those who are anxious to be cured is the application of hypnotic suggestion.

Cockroaches

Q.—What is the best way to combat the beetle pest?

A.—Repeated applications of powder are the only measures that can be used against cockroaches (misnamed "beetles" or "black-beetles"). Of the powders available for civilian use, sodium fluoride is the best, but may be considered too dangerous to be used in kitchens without careful supervision. Boric acid or borax are the best alternatives: they must be very finely ground to be effective.

The powders are blown into crevices or dusted round the corners of the floor where the roaches are believed to be hiding.

Prescribing a Scheduled Poison

Q.—I am asked by a local colliery to furnish a prescription for sulphacetamide 10% or 30% to be used as eye-drops by their unsupervised ambulance-room attendant. As this is a scheduled poison, am I in order in issuing such a prescription, and, if so, to whom should it be addressed?

A.—The Poisons Regulations provide for the purchase by a firm of poisons to be used in the course of their business, but, in the view of the Pharmaceutical Society, this does not apply to poisons required for medical purposes in the treatment of members of the staff. An employee treated in an ambulance room is in the same position as any member of the public, and any prescriptions to which the Poisons Regulations apply should be made out in the name of the patient. The alternative is for the doctor to order the eye-drops to be supplied to him for use in his practice just as though he were stocking his own dispensary. He will then be responsible for the use to which the eye-drops are put afterwards.

Keeping Dentures Clean

Q.—I would like to know the recipe for removing from dentures persisting brown deposit. I have tried dilute HCl without effect, and keep them in water containing a few drops of Milton.

A.—The brown deposit on the dentures is probably tartar which has become saturated with nicotine. This can be removed only by scraping with an old scalpel until the surface of the denture is reached. Better still, let the dental surgeon have them for a hour, as he has facilities for cleaning and polishing. The proper way to keep a denture clean is to scrub it night and morning with soap, using a stiff nail-brush or tooth-brush. Chemical cleansers are in the long run harmful to the base material and should not be used as a routine. Ordinary whitening is excellent for keeping a high polish on the surface, and is best applied with the brush after the soap has been washed away. Some mouths deposit tartar and stain more readily than others, and this hard scrubbing may be necessary after every meal.

Campden Method of Preserving Fruit

Q.—What happens if Campden solution tablets, containing 48 SO₂, are used for preserving fruit, and, later on, the whole boiled before use? Is the SO₂ the active thing in the tablet, and is the SO₂ driven off by the boiling, or what exactly happens?

A.—Campden tablets are made from sodium metabisulphite. The compound reacts with the acids in the fruit juice and SO₂ is formed. If the vessel containing the fruit is tightly stoppered, most of the SO₂ remains in solution at room temperature, and it is this SO₂ in solution which prevents bacterial growth. One part in 1,000 is effective, and if the tablets are used according to the prescription this strength is attained. When the vessel is opened and the fruit is boiled, as it should be before use, the SO₂ is driven off, and the sodium salts of the acids in the fruit juice remain behind. Incidentally, therefore, Campden tablets, while acting as a preservative, also tend to neutralize the acidity of the fruit, so that it may be stewed with less sugar.

LETTERS, NOTES, ETC.

Diathermy in Eye Disease

Mr. FRANK W. LAW, F.R.C.S. (London, W.1), writes: May I be permitted to say that I think the opinion expressed in the reply to the inquiry for reliable information about the use of diathermy in eye disease (Oct. 2, p. 442) was unjustifiably lukewarm? Further, your few notes hardly answer the question asked. Your correspondent might find some answer to his query in the following references: Law, *Trans. Ophthalm. Soc. U.K.*, 1933, 53, 474; Law, *Brit. phys. Med.*, Dec., 1936; Law, *ibid.*, July, 1940, p. 122; Lloyd, *Trans. Ophthalm. Soc. U.K.*, 1939, 59, 181; Phillips, *ibid.*, p. 193. It is obvious that I cannot express an opinion on the reliability of the information contained in most of these!

Proof of Negligence

Mr. WALTER SIMPSON (Bristol) writes: The "conventional course suggested by your correspondent (Aug. 7, p. 183) is not now permitted. Recently the Court of Appeal ruled that counsel cannot (1) submit there is no case to answer and (2) subsequently call witnesses if the judge rules to the contrary. If defendant relies on 1 submission that no case has been made out he cannot subsequently call witnesses to disprove the charge. My authority is Mr. Justice Hilbery, King's Bench Division, *Stacey v. Clarke*, Col., July, 1942.

Transparent Disinfectants

Dr. J. E. J. PALSER (Theydon Bois) writes: In the paper by Lieut. Col. R. K. Debenham on war surgery in the Middle East (*Journal*, Aug. 21, p. 223) I was interested to read his warning against putting dentures into a preparation in which they are out of sight and may be lost. This warning would apply also to the immersion of surgical instruments in a similar preparation. I may point out, however, that Iysantol, an effective non-irritant disinfectant, with a Rideal-Walker coefficient of about 4, will bear dilution with as much as 15 parts of tap water without producing more than a slight opacity and if diluted with distilled water in any proportion forms a perfectly transparent solution.

Hyperidrotic Axillae

Dr. D. M. MACDONALD (Arnside) writes: Should the treatment suggested under the above heading in the *Journal* of Oct. 2 (p. 44) fail, an almost certain remedy will be found in the use of the constant current (20 milliamperes) twice a week for from ten to twenty minutes. The negative pole is applied to the affected area.

Disclaimer

Dr. K. I. E. McLEOD (Dingwall), whose letter, printed in the *Journal* of Sept. 25, was quoted by several of the national newspapers, wishes to disclaim any knowledge of how this quotation was made. He expresses alarm at the frequency with which letters to scientific journals are quoted in this manner without the knowledge or permission of the writer.

STUDIES IN VITAMIN B DEFICIENCY WITH SPECIAL REFERENCE TO MENTAL AND ORAL MANIFESTATIONS

BY

A. GREY CLARKE, B.Sc., M.B., D.P.M.

Medical Registrar, West End Hospital for Nervous Diseases, London

AND

F. PRESCOTT, M.Sc., Ph.D., A.I.C., M.R.C.S.

Wellcome Research Institution, London

(WITH PHOTOGRAPHURE PLATE)

Clinical descriptions of the results of a deficiency of members of the vitamin B complex are common in American published work but scanty in the medical literature of this country. Cheilosis due to riboflavin (vitamin B₂, lactoflavin) deficiency has been described in England by Wilson (1942) and Duckworth (1942); and Deeny (1942) has reported on 16 cases of pellagra in Northern Ireland, where, he says, mild forms of the disease are relatively common and usually pass unrecognized, the patient being diagnosed as suffering from neurasthenia, dyspepsia, or eczema. Studies of pellagra in England between 1934 and 1939 were made by Davies and McGregor (1939), who reviewed 16 cases. Since submitting this paper for publication Hardwick (1943) has described pellagra associated with chronic psychosis in 10 patients in an English mental hospital. Egaña *et al.* (1942) and Johnson *et al.* (1942) have described the effects on human volunteers of experimental diets deficient in the vitamin B complex. These include easy fatigue, loss of ambition and efficiency, poor appetite, insomnia, constipation, muscle pains, and slight anaemia in persons in sedentary occupations. The literature on the clinical manifestations resulting from a deficiency of the B group of vitamins has been reviewed by Bicknell and Prescott (1942).

Psychoneurosis and Dietary Deficiency

We have recently seen 17 cases of vitamin B complex deficiency in patients treated primarily for nervous disorders. This represents 2% of the patients seen by us in the outpatient department of the West End Hospital for Nervous Diseases. Originally they were mostly classified as suffering from functional nervous disorder, and with one exception were women. The parallelism between the manifestations of a deficiency of the vitamin B complex and those of psychoneurosis is seen from the following list. All are likely to be met with in the psychoneurotic; those in italics may result from a deficiency of the vitamin B complex.

General: *Fatigue, anorexia, indigestion, constipation, diarrhoea, dizziness*

Circulatory: *Tachycardia, palpitation, shortness of breath*

Vasomotor: *Pallor, blushing, sweating*

Nervous system: *Headache, backache, insomnia, photophobia, hyperacusis, noises in the head, vertigo, hyperaesthesia, paraesthesia*

Mental symptoms: *Inability to concentrate, self-consciousness, depression, phobias, anxieties*

So close is the parallelism that early cases of pellagra—which is a multiple deficiency disease—are often diagnosed as “functional” by those unacquainted with the early manifestations.

A patient may suffer from a general dietary deficiency and exhibit only the manifestations of a deficiency of the vitamin B complex in the early stages. This is partly because these manifestations are the first to show. The results of a deficiency in vitamin A, C, D, or K are not so obvious clinically: special laboratory tests must be employed for their detection unless gross deficiency is present. The B vitamins, being water-soluble, are not stored in the body to any extent, and diet poor in these vitamins give rise to deficiency symptoms in three months or less (Vedder, 1940). Although it is convenient to split up the B vitamins for purposes of classification, an uncomplicated deficiency of one of them does not exist clinically, because they occur together in Nature and no selected combination of foods is entirely lacking in any one of them. There is no such thing as pure vitamin B₁ deficiency unless induced experimentally, because if the diet is deficient in vitamin B₁, it will also be deficient in the other B vitamins such as riboflavin, nicotinic acid, pyridoxine, pantothenic acid, etc.

In our cases certain features were common to all. All the patients gave a history of a poor diet, or lack of appetite due to mental or physical causes, or a condition necessitating dieting (peptic ulcer, hypertension) or interfering with absorption (vomiting, typhoid). Many of the patients lived alone, or had grown-up families out at work all day, so that they did not prepare proper meals. Others had no appetite and subsisted on occasional snacks, which consisted largely of refined carbohydrate foods. A vicious circle was thus created because these foods contain little of the vitamin B complex, and an increased consumption of carbohydrate increases the need for B vitamins; and lack of the latter produces further loss of appetite. Many of the patients did not eat meat, and few included adequate milk or cheese—all rich in the vitamin B complex—in their diet. A general preference was expressed for white bread which is a poor source of the vitamin B complex, much of the vitamin B₁ and riboflavin being removed in the milling.

All the patients showed some of the signs and symptoms of functional nervous disorder—most commonly depression, headache, insomnia, and loss of appetite. Other symptoms were lack of energy, fatigue on slight exertion, breathlessness, inability to concentrate, and nervous dyspepsia. There was only one case of psychosis in the series, probably because such cases more commonly go to observation wards in the London area.

All our cases showed a marked improvement in their “psychoneurotic” symptoms, and the majority a complete disappearance of these symptoms, after treatment with the vitamin B complex. Except in the one case admitted, the environment was unchanged. We think that in most of these cases the condition was determined to some extent by the wartime marginal diet but actually precipitated only when mental or

physical factors led to loss of appetite or impaired absorption. Case I, which was treated as an acute emergency, illustrates the need for a mental ward in general hospitals. Two cases at a later stage reported from a mental hospital by Parfitt (1936) failed to make a complete recovery on treatment with the B vitamins, although their improvement was dramatic.

Oral Lesions

All the patients showed signs and symptoms of nicotinic acid deficiency (glossitis, and depression or other mental symptoms), and nearly all showed one of the signs originally considered specific for riboflavin deficiency (angular stomatitis or cheilosis). The value of cheilosis as a specific sign of riboflavin deficiency has, however, recently been questioned, and it appears that this may occur independently of a nutritional deficiency. It may result from other causes, such as poorly fitting dentures, which result in malocclusion (Ellenberg and Pollack, 1942), and even from sensitivity to lipstick or chewing-gum (Miller, 1941; Hecht *et al.*, 1939). We have also observed cheilosis in a patient with post-encephalitic parkinsonism, in which the condition was presumably due to the dribbling of saliva and not to a nutritional deficiency: the diet was adequate and there were no other manifestations of nutritional disease. A number of cases of cheilosis described in America failed to respond to riboflavin, but did to other members of the vitamin B complex, such as nicotinic acid, pyridoxine, or yeast (Machella, 1942; Machella and McDonald, 1943). Some, however, failed to yield to vitamin therapy of any type. The cheilosis in two of our cases did not respond to treatment with riboflavin and the vitamin B complex.

Signs and symptoms of peripheral neuritis, which are generally considered to be the result of vitamin B₁ deficiency, were present in only four cases.

Treatment

The patients were treated with supplements of vitamin B₁, 3 to 9 mg. daily, riboflavin 3 to 9 mg. daily, and nicotinic acid 100 to 500 mg. daily. The patients were also instructed to take as much meat, milk, cheese, and whole grain in their diet as possible and to take proprietary wheat-germ or yeast preparations when obtainable. American workers (Sydenstricker, 1941) have pointed out that intensive treatment with one factor of the vitamin B complex may provoke symptoms of deficiency in another factor. It is therefore advisable when giving intensive therapy with one factor to give supplements of wheat germ or yeast. All the patients except two responded to treatment. One suffered from mental retardation due to depression, and it was difficult to obtain co-operation. Three of the patients relapsed after periods of from two to five months without treatment and presumably on return to their deficient diet. Two of these responded to further treatment.

Seven selected case records are given below. They were chosen for their severity or long duration. The average age of the patients was 53, the youngest being 28. Most of them were women over 50. Photographs before and after treatment were taken of five patients, but on account of lack of space only two sets are reproduced on the Plate.

Case I

Female aged 63. Psychosis, polyneuritis, glossitis, microcytic anaemia. On March 30, 1942, she complained of depression, gradually increasing during the past four months, and for the past week had shown marked psychomotor retardation, with delusions of guilt, disease, and poverty, and impairment of memory, especially for recent events. Tongue red and dry, with flattening of papillae along lateral margins. Knee- and ankle-jerks, and vibration sense in legs, absent. Incontinence of urine on admission. Heart slightly enlarged. B.P. 170/110. Hb 64%; R.B.C. 3,500,000, and slightly microcytic. Relative lymphocytosis (37%). Blood urea and kidney function were normal.

Nicotinic acid up to 300 mg. daily, vitamin B₁ 10 mg. daily, vitamin C 50 mg. daily, and ferrous sulphate 3 gr. b.d., were given with dramatic improvement in her mental condition in the first 48 hours. While in hospital she developed mild diarrhoea (no pathogenic organisms found), which was probably due to increased bowel motility after administration of nicotinic acid and vitamin B₁. Later she developed tonsillitis, submaxillary adenitis, and an erysipeloid condition of the face. Treatment with sulphanilamide was successful.

On April 22, 1942, she was discharged feeling very well. When seen three months later she had no symptoms. There was a partial return of one knee-jerk, but ankle-jerks were still absent. Hb 80%, R.B.C. 4,750,000.

Comment.—This case presented the symptoms of an acute depression together with acute organic mental symptoms and peripheral neuritis. The history obtained from the patient and her sister revealed that she had had two previous attacks of depression, five years and one year previously. Her diet for nine months before admission did not include meat. She ate white bread. Her sister, on the same diet, remained well. It is likely that the condition was precipitated in this patient on a borderline diet by a cyclothymic depression with loss of appetite. A vicious circle was set up, the poor appetite leading to diminished intake of food and hence of the B vitamins, lack of which resulted in the onset of the deficiency symptoms—glossitis, polyneuritis, acute psychosis, and possibly anaemia.

Case II

Female aged 73 (Plate, Figs. 1 and 2). In 1936 she was treated for rheumatoid arthritis, obesity and hypertension, and varicose veins. B.P. 180/80. Breathlessness on exertion. She was given potassium bromide and iodide and sodium salicylate, and told to omit meat from her diet on account of hypertension. Her main article of food was bread-and-butter (margarine?). She had had no meat for three years. She also dieted for her obesity. Brachial neuritis was present early in 1942.

We saw her on June 15, 1942. There was then severe angular stomatitis with considerable crusting at corners of mouth. The tongue was sore, particularly on eating and swallowing, and felt as if scalded. On examination the tongue was very red and fissured (Fig. 1), the skin of the arms and neck was pigmented and coarse, and there was an erythematous rash with denudation and pruritus of the skin around the vulva and on the skin from the vulva to the knees. She was given 9 mg. of riboflavin daily.

In one week the lesions at the corners of the mouth were considerably improved and within a fortnight they had healed, but the pigmentation of the skin and the glossitis were unchanged. In addition to riboflavin 10 mg. daily, 400 mg. of nicotinic acid in divided doses and 6 mg. of vitamin B₁ were now given, and the patient was instructed to eat a full diet, including yeast and wheat-germ preparations. Within a fortnight the pigmentation over the neck, arms, vulva, and legs had almost disappeared, and the tongue no longer felt hot and as if scalded. The dosage of nicotinic acid was reduced to 250 mg. daily. After five weeks all the lesions had healed and the patient looked and felt much better. She no longer complained of breathlessness, sore tongue, or pruritus. After ten weeks' treatment the tongue was more normal in colour and many of the fissures had healed (Fig. 2). The patient was kept under observation for a total period of three months. Improvement was maintained, and at the end of this time she was discharged.

Comment.—In this case the lesions of the lips healed with riboflavin, which had no effect on the glossitis. This responded only to nicotinic acid. One very noticeable result of the treatment was the improvement in mood.

Case III

Female aged 70 (Figs. 3 to 6). Presenting complaints: depression, insomnia, memory impairment, glossitis, irritation, and rash on neck and lower extremities. Noted for six months. Before being seen by us she had been treated unsuccessfully for eczema for six months. Examination showed B.P. 185/95, a red smooth tongue, and shiny red, cracked lips. There was a scaly pigmented dermatitis on the exposed situations, particularly the neck, face, elbows, vulva, arms, thighs, and flexures (Figs. 3 and 5), with a seborrhoeic dermatitis of scalp and ears. The face was oedematous and pigmented, particularly around the eyes. The heart was enlarged, with a mitral systolic murmur; pulse 56; frequent extrasystoles, photophobia, and lacrimation. The patient had a very poor dietary history: she lived alone and had no appetite.

Sept. 16, 1942.—Treated with 400 to 500 mg. nicotinic acid, 9 mg. vitamin B₁, and 3 mg. riboflavin daily, and a yeast concentrate. Much improvement within a week. Marked improvement after 14 days.

Sept. 30.—Patient more active and less depressed. Swelling of face and eyes reduced. Pigmentation and dermatitis around neck, face, and elbows disappearing. Tongue not so red and sore. No photophobia or lacrimation.

Oct. 14.—Tongue no longer sore, and dermatitis almost disappeared, except on scalp and behind ears (Figs. 4 and 6). This was of the seborrhoeic type and unlike that on the face, neck, and arms.

Oct. 28.—Appetite better; considerable subjective improvement. Vitamin C and thyroid 1/2 gr. daily included in treatment. No stomatitis or glossitis, patient no longer depressed. Improvement continued for a further two months with vitamin treatment, but seborrhoeic dermatitis of scalp and behind ears still persisted, although responded later to local treatment.

Comment.—This case, which we consider to be one of mild lagra (dermatitis, depression), was complicated by a dermatitis of seborrhoeic type, on the scalp and ears, which, unlike the dermatitis elsewhere, failed to respond to treatment with the vitamin B complex, but did so to local applications.

Case IV

Female aged 56. Presenting symptoms: insomnia, fatigue, headaches, forgetfulness, inability to settle down, and angular stomatitis. Poor appetite. Diet consisted of much bread and potatoes, meat or cheese, and a little milk with tea. History of typhoid fever. Diagnosed in 1931 as psychasthenic. Stomatitis treated successfully for eleven years with local applications. Nervous symptoms treated with phenobarbitone, and bromide and strychnine.

Oct. 14, 1942.—First seen by us. Crusted lesions at corner of mouth (angular stomatitis). Feeling of grit in the eyes and some degree of photophobia. Coarse, greasy, seborrhoeic skin of face, particularly over nose, naso-labial folds, and chin. Sore tongue, with peppery feeling when eating or sucking. Denudation of skin at lower lip. Tongue very red, clean, raw, and swollen. Mild degree of anaemia (Hb 88%, R.B.C. 4,790,000). Treated with riboflavin 3 mg. t.d.s., nicotinic acid 300 to 400 mg. daily, vitamin B₁ 3 mg. t.d.s., and wheat germ.

Oct. 28.—Mouth lesions and sore tongue considerably improved. Photophobia and gritty feeling in eyes gone. Diet improved.

Nov. 11.—Improvement maintained; eating well, facial skin not greasy and coarse. Angular stomatitis gone. Dosage of vitamins reduced to riboflavin 2 mg. t.d.s., nicotinic acid 300 mg. daily, and vitamin B₁ 3 mg. b.d.

Dec. 9.—Tongue no longer sore. Appetite good. Much improved mentally. Sleeping well. Tiredness and headaches gone.

Comment.—The "psychoneurotic" symptoms, seborrhoea, glossitis, and angular stomatitis had been present for 11 years and resisted general treatment. After two months' treatment with vitamin B complex and improvement of the diet local and mental symptoms disappeared.

Case V

Female aged 63. In 1938 diagnosis of glossitis, psychoneurosis, and hypertension made. Poor appetite, indigestion, pallor, dry skin, scanty hair, oedema of feet. B.P. 230/115. Once a patient at a mental hospital. Treated with bromide, valerian, and thyroid. The glossitis subsequently treated with chromic acid, zinc sulphate ointment, and finally vaseline, without success. Diagnosis of chronic treptococcal tongue made by clinician of another hospital.

Seen by us on Nov. 2, 1942. Angular stomatitis present. Tongue very red, raw, and atrophic. Lips smooth, very red, and denuded of epithelium. Scaly pellagroid dermatitis on face. Questioning revealed poor dietary history. The patient ate only little meat and milk. Did not cook for herself. R.B.C. 5,000,000; Hb 78%. Treatment with riboflavin 5 mg. t.d.s., vitamin B₁ 3 mg. t.d.s., and nicotinic acid 400 mg. daily; advised to improve diet. A week after the tongue and lips were not sore and inflamed. After another 14 days the facial dermatitis had gone and the angular stomatitis had almost disappeared. Although the tongue had improved subjectively, it was still red and fissured. Dosage of vitamins reduced. On Dec. 9 there were no signs of angular stomatitis, and the mouth and tongue were no longer sore and dry. The tongue was less fissured and more normal in colour.

By June 7, 1943, after five months without treatment owing to inability to attend the hospital, the patient had relapsed and her symptoms were as bad as ever. On June 21, after 14 days' treatment as described above, her condition had improved considerably.

Comment.—This was the first improvement in the mouth and lips for four years. The patient had also improved mentally; she was less tired and more cheerful. On stopping treatment with the vitamin B complex for five months the soreness of the tongue and mouth returned. This responded to treatment again.

Case VI

Female aged 70, seen by us on Dec. 30, 1942. She was anxious and depressed, had had pins-and-needles in hands and feet for five months, and dyspepsia. B.P. 165/85. Examination showed a flat, smooth, swollen, very red tongue denuded of papillae, cracks at corners of mouth with crusting, vertical fissuring of lips, and

pale mucous membranes. Noted for six months. No meat, eggs, cheese, and only a little milk in diet. Much bread and potatoes. R.B.C. 3,760,000; Hb 78%.

Treated with ferrous sulphate, riboflavin 6 mg. daily, nicotinic acid 200 mg. daily, and vitamin B₁ 9 mg. daily, with instructions to eat a full mixed diet, including wheat germ and yeast. Angular stomatitis healed in two weeks, and tongue nearly normal in colour. No dyspepsia; eating better, and no depression. After a month's treatment anxiety had gone; the patient was eating much better and looking better. Mouth and tongue lesions had disappeared, although the tongue still appeared smooth and flat. Papillae of tongue reappeared after five months' treatment. Paraesthesiae disappeared. Relapsed after two months without treatment. Admitted as an in-patient to a general hospital suffering from psychotic depression and delusions. Discharged well after four weeks' treatment.

Case VII

Female aged 56, nurse from a South Coast hospital, seen May 6, 1943. Complained of sore fissured tongue with peppery feeling of one year's duration, depression, dry cough, dyspnoea on exertion, difficulty in maintaining balance. Not previously "nervous"; went through air raids as night sister. Very poor dietary history—denatured cereals, white bread, and no meat. On examination tongue very red and deeply fissured; upper lip cracked at mucocutaneous margins; no Rombergism, but marked diminution of vibration sense in both legs. B.P. 150/100; moist sounds on inspiration at bases of both lungs; hypochromic anaemia. No dermatitis, subcutaneous oedema, or demonstrable cardiac abnormality. Unwilling to enter hospital or to co-operate in further investigations. Treatment as in former cases with riboflavin, nicotinic acid, vitamin B₁, and in addition ferrous sulphate for anaemia. On May 20 she was much less depressed, the tongue was a dull red and no longer sore, and there was no ataxia. By July 1 objective signs had disappeared except for residual fissures on the tongue. The patient remained at work during treatment.

Summary

Seventeen cases of a deficiency of the vitamin B complex, associated with oral lesions and mental symptoms, are reported. One was an acute psychosis, and a few had polyneuritis.

Although in most of these cases the condition appears to have been determined to some extent by the wartime marginal diet, it was actually precipitated only when mental or physical factors led to loss of appetite or impaired absorption. These factors included adherence to special diets (e.g., for peptic ulcer, obesity, and hypertension) and conditions interfering with the absorption of food (vomiting and gastro-intestinal diseases).

The striking features were the regular occurrence of the oral lesions, which were attributed to nicotinic acid and riboflavin deficiency, and the invariable presence of symptoms usually regarded as psychoneurotic, but which cleared up with vitamin B therapy without alteration of the environment or special psychological treatment.

A parallelism is drawn between some of the manifestations of the psychoneurotic syndromes and those of a deficiency of the factors of the vitamin B complex.

We wish to thank Dr. C. Worster-Drought, clinical director of the West End Hospital for Nervous Diseases, for his encouragement to publish these cases, and also Dr. Peter Tresise, R.M.O., for his help and enthusiasm with Case I. We are also indebted to Dr. Carnegie Dickson for the pathological work.

B. Rao and C. V. Natarajan (*Ind. med. Gaz.*, 1943, 78, 297) record an outbreak of smallpox in the Kolar Gold Fields in the late autumn and winter of 1942. The case mortality was high, being 33%. All the patients were given sulphanilamide by mouth without any effect on the course of the disease or the mortality.

ENDEMIC TYPHUS FEVER IN DIEGO SUAREZ, MADAGASCAR

BY

C. G. BAKER, M.D.

Major, R.A.M.C.; Medical Specialist

G. T. L. ARCHER, M.B.

Major, R.A.M.C.; Pathologist

AND

G. B. MITCHELL-HEGGS, M.D.

Lieut.-Col., R.A.M.C.; in Charge of Medical Division

The map showing the recent distribution of the fevers of the typhus group in the Epidemiological Report of the Health Section of the League of Nations, 1936, suggests that these have not been recorded in Madagascar, and the local French public health report, 1940, states that this group of diseases does not occur on the island. It is therefore felt that the following series of cases among Service units, though small, justifies a special record.

The general hospital was functioning with limited equipment in Madagascar for several months after May, 1942. There

were a considerable number of cases with pyrexia of uncertain origin, with and without a rash, to which an accurate label could not be attached, as no agglutinable suspensions were available. Soon after the arrival of the suspensions a patient was admitted to hospital suffering from severe headache, drowsiness, backache, pains in chest, and a productive cough. This case was first diagnosed as bronchopneumonia, but sulphapyridine had no effect, for his fever continued and he remained seriously ill. For this reason, and despite negative blood films, it was thought that he might have malaria, but well, and so was given quinine. On the seventh day a macular rash developed, and his bloated appearance with suffused face taken in conjunction with the course of his illness, led to a suspicion that the case was one of typhus (C. G. Baker). This was confirmed by the Weil-Felix test (G. T. L. Archer). Patients in the hospital with indefinite fever—in some cases with a rash and severe malaise, in others only slightly ill, all from the same unit and area—were immediately examined again, and blood agglutination performed.

The early results of Weil-Felix examination were as follows:

- Case 1: OX19, OX2, OXK, 1/100 on 11th day
 „ 2: OX19 1/400, OX2=0, OXK=0, on 12th day
 „ 3: OX19 1/800, OX2 1/200, OXK 1/100, on 18th day
 „ 4: OX19 1/100, OX2 1/100, OXK 1/20, on 12th day

TABLE I.—Summary and Analysis of Cases

(On grounds of economy detailed notes of these cases are not included in the report, but are available on request)

— = No record.

The question of a vector arose. Nothing definite could be deduced from the patients' histories, but within the limited means at our disposal as a stationary hospital some investigations were made, and it was found that:

1. *Lice*.—None of the patients were louse-infested, but all had been bitten, of course, by insects recently.
2. *Fleas*.—Fleas of two puppies which had frequented the location, as from rats found in the native huts which were at one time used as sleeping quarters by a few of the men for a short period, and fleas from rats living in an ammunition dump which had been guarded in turn by most of the patients were possible vectors. *Ctenopsylla cheopis* and *X. braziliensis* were found on rats caught in the neighbourhood.
3. *Mosquitoes*.—Three cases developed malignant tertian malaria while in hospital.
4. *Ticks*.—Ticks infested almost every dog in the district.
5. An unknown vector remained a possibility.

All respective observations, investigations, and treatment were controlled by medical specialist, pathologist, and officer in charge of the medical division of the unit. The pathologist had only a very limited supply of agglutinable suspensions, so as to choose the time of taking the specimen with considerable care. These three officers are convinced that a fever with definite clinical picture similar to that seen in cases of the typhus group found elsewhere, supported by appropriate pathological tests, has occurred among people living in the region of Col's Hill (near Diego Suarez), Sakaramy, and Orangea. In spite of the official views expressed in the first paragraph it may well occur elsewhere on the island.

Incubation Period

This could not be fixed accurately, as most of the patients reached the main site, Col's Hill, on May 31 but developed their illness at different times (Table I). The dates of insect bites were noted where possible; the incubation period appeared to be 10 days in Case 5, 16 days in Case 2, possibly 1 month in Case 3 (who stated he had not been bitten for that period), and 2 months in Case 6 (who also stated that he had not been bitten recently but had sustained an infected abrasion two months before the onset of the illness). Subtertian malaria infection occurred at the onset of the illnesses in Cases 8 and 9, but towards the end in Case 7. A patient from his site who attended the skin department on account of bites on the thigh and waist region of the abdominal wall, such as most of these patients had had, was admitted and kept under observation to see whether an incubation period between his bite and the fever could be ascertained, but his Weil-Felix reaction never rose above OX19 1/40, OX2 1/20, OXK 1/40.

The prodromal period appeared to be about 2 days. It was not present in all cases, being absent in Cases 1, 5, and 10. It was of 1 day's duration in Case 7, 2 days in Cases 3, 4, and 5, 3 days in Case 2, and 4 or 5 days in Case 9. The symptoms during this time were unusual lassitude, fatigue, and sleepiness very early at night, and a headache early in the morning, which gradually passed off during the day but returned in the evening.

Onset of Fever and Illness

This was gradual in half the cases and sudden in the remainder. The invasion symptoms included headache, pains in the chest and epigastrium, severe backache, dizziness and falling to the ground, and rigors or shivering attacks. Severe headache was the most common symptom, starting in the frontal region, then being noted in the occipital region, and finally in the whole head.

The main features of the established illness appeared to be a continuous high fever for about 14 days, temperature varying between 100° and 104° F., and pulse between 80 and 100. Sweating was marked throughout the febrile period and was notable for a characteristic heavy musty odour (quite different from that of patients in hospital at the time suffering from malaria, paratyphoid A, dengue, fevers, etc.). The patients were drowsy, lethargic, and uncooperative; it was an effort to protrude the tongue for inspection. There was puffiness around the orbits, with conjunctival suffusion, blotchy bloated appearance, and sleepy expression. The main ocular symptoms were heaviness of the upper eyelids, pains behind the eyes, pain on moving the eyes to the right or left, and photophobia.

Headaches were very similar, usually starting in the frontal region, spreading to the occipital region and later to the whole head. They were compared with a heavy weight pressing on the head, and were not associated with a marked throbbing or bursting sensation. Early in the morning they were most severe, diminishing during the day but increasing late in the evening, and often keeping the patient awake. Backache was usually in the lumbar muscles, but did not occur between the shoulders. The limb pains were in some ways like those met with in dengue—frequent in the shins and knees and muscles of the upper limbs, biceps and supinator longus being picked out particularly in Case 8. A common finding was a dry mouth and tongue, but sordes was present only in the most severe cases.

A rash appeared in more than half the cases on or about the fifth day. It was noticed on the chest and flanks at first. The full distribution in some included face, limbs, palms, and soles. The rash consisted of small red pinhead-size papules and red macules varying from 1 to 3 mm. in diameter. At first these faded on pressure with a central red point in a few, but after a few days darkened, and on diascopic examination most showed a residual brown pigmentation. The darkening process continued until the lesions were dark brown, and then gradually faded away. Lesions of different colour were present at the same time, and fading ones gave a clear

impression of subcuticular mottling. The average duration corresponded with the period of high fever, 102° and above, lasting from 7 to 14 days. It was associated with a lineal conjunctival congestion, especially between the cornea and the outer canthus. Epistaxis occurred in 4 cases during the early stages of the fever, and vomiting occurred in 2, but there was no haematemesis.

Chest symptoms and signs were a pronounced feature. Case 1 was first diagnosed as a simple bronchopneumonia. Case 10 had a bronchopneumonia with blood-stained sputum, and in the remaining cases productive cough with signs of bronchial involvement of greater or lesser degree occurred. Involvement of the central nervous system was not marked. Headache and insomnia were common, and the most seriously ill were irrational and uncooperative, with subsequent partial amnesia; but apart from loss of abdominal reflexes and only sluggish tendon reflexes no clinical signs were found. The spleen was palpable in 4 cases in the first week and tender in 1. The lymphatic glands of the neck and axillae were slightly enlarged to the size of a pea in 4 cases and to a greater degree, and particularly in the tonsillar group of cervical glands, in the 2 cases in which there was an associated pharyngitis. Tenderness was absent in most instances, Case 1 being the exception.

Treatment was systematic; morphine was effective.

Pathological findings were as follows. Albuminuria in the severe cases, with red blood corpuscles or casts in deposits, and a secondary anaemia in two cases: Case 3—R.B.C. 3,300,000; W.B.C. 7,200 (polymorphs 60%, lymphocytes 36%, monocytes 4%); Case 4—R.B.C. 3,300,000, W.B.C. 5,200 (polymorphs 68%, lymphocytes 26%, monocytes 5%, eosinophils 1%).

Notes on Table II

The technique used was that of Felix, agglutination in round-bottom tubes at 37° C. The method of reading, however, was modified, after a preliminary examination, by shaking the tubes and observing the end-point of granularity. This was done in view of the fact that many of the tubes in use were not hemispherical at the bottom. Dreyer's technique was not employed, as Dreyer's tubes were not available. On receipt of a few Dreyer's tubes, however, two pairs of tests were carried out in parallel, using the two methods. The results were identical.

The + sign after the titre shown indicates that though the test was not carried further the result on the last tube suggested that the limit of agglutination had not been reached. 0=less than 1/20, the lowest dilution used.

The results, showing comparatively low titres for OX19, with in most cases marked coagglutination for OX2, and, in some, lesser coagglutination for OXK, would appear to indicate a group reaction. They differ from those to be expected in epidemic or endemic (murine) typhus or in mite typhus, while in South African tick typhus the OXK agglutination usually predominates. The results, however, appear to resemble those which occur in the "OX19 Group" of Indian cases (Boyd), 1935.

Vector and Possible Animal Reservoir.—No laboratory investigation was possible on these points, as there were no guinea-pigs available for inoculation experiments with preparations from possible vectors, and the continued shortage of agglutinable suspensions made it impossible to do serological tests on animals.

We wish to thank Lieut.-Gen. Sir A. Hood, Director-General, Army Medical Services, Major-Gen. A. G. Biggan, the Consulting Physician, and Col. J. F. W. Sandison, Officer Commanding the unit, for permission to publish this record.

TWO CASES OF ANURIA DUE TO SULPHAPYRIDINE CALCULI SUCCESSFULLY TREATED BY URETERIC CATHETERIZATION

BY

H. BURT-WHITE, M.D., F.R.C.S.

Major, R.A.M.C.

AND

A. G. JOHNSON, M.R.C.S.

Major, R.A.M.C.

The seriousness of haematuria and anuria complicating sulphapyridine therapy is well recognized, and a number of cases have been reported both in America and in Great Britain. The renal complications of sulphapyridine therapy were well reviewed by Laird (1941) when reporting five cases of haematuria and one of anuria. More recently the literature has been reviewed by Carson and Smith (1942) and by Benson and Percival (1942), who reported respectively the necropsy findings in a fatal case and a case treated successfully by ureteric catheterization.

In the two cases described below relatively small doses of sulphapyridine—9 and 13 g. respectively—were administered and in both cases haematuria followed by anuria resulted. Both cases were in hospital before haematuria developed, at first were ambulatory. A high fluid intake was encouraged but the volume was not measured. Both patients were a males of good physique, admitted to hospital on account of uncomplicated gonococcal urethritis.

Case I

A man aged 28 was admitted on Nov. 17, 1941. He was given 4 g. of sulphapyridine daily for two days, and on the morning of the third day received 1 g. Soon after the last dose he passed deeply blood-stained urine. Later in the day vomiting and severe renal pain were noted and no more urine was passed. As the patient persisted he was transferred to the surgical department and a cystoscopy was performed after 24 hours' anuria.

The bladder contained a small amount of blood-stained urine. The bladder wall appeared normal except for a well-marked ureteric orifice on both sides; that on the left side made the passage of a ureteric catheter impossible. A catheter was passed on the right side and the renal pelvis was washed out. On his return to ward an intravenous drip saline was started, this being continued for two days. A few drops of blood-stained urine drained through the catheter, and 24 hours later he was cystoscoped again. Two ureteroceles were more pronounced, and further attempts to catheterize the left ureter failed; but on catheterizing the right ureter blood and sulphapyridine crystals were seen to escape into the bladder, urine drained through the catheter, and in the subsequent 24 hours he passed 100 oz. of urine through the catheter and urethram. The catheter was removed after 18 hours. His symptoms rapidly abated, and on discharge from hospital two weeks later his urine was normal. The highest blood urea was recorded on the day of the second cystoscopy, being 72 mg. per 100 c.cm.

Case II

A man aged 27 was admitted on Oct. 14, 1942. He was treated with sulphapyridine, and received a total of 13 g. between admission and 6 a.m. on Oct. 17. At 6.30 a.m. on Oct. 17 he started passing blood-stained urine, 5 oz. being passed between that time and 11 a.m. He then complained of severe pain in both loins and persistently vomited stomach contents containing changed blood. At 7 p.m. his condition had deteriorated, and as he had not passed urine since 11 a.m. he was transferred to the surgical department where a cystoscopy was performed. The bladder contained about 1/2 oz. of practically pure blood together with a large amount of sulphapyridine crystals, there were small petechial haemorrhages in the bladder mucosa, both ureteric orifices were congested, and a pencil of sulphapyridine crystals was seen protruding through the left ureteric orifice. On passing a catheter up the left ureter crystals, debris, and blood were seen to escape. A catheter was then passed up the right ureter for only about 2.5 cm. On removal from the theatre he was started on intravenous drip saline, which was continued for three days till the vomiting ceased. Five oz. of blood-stained urine loaded with sulphapyridine crystals drained from the left ureter and none from the right in six hours, after which the left catheter became blocked.

At 10 a.m. on Oct. 18 both catheters were removed and found to be blocked with blood and crystals. Fresh catheters were now passed up both ureters, and both ureteric orifices were observed to be more congested. Attempts were made to wash out the renal pelvis with normal saline, but although 5 c.cm. was injected through each catheter no fluid could be withdrawn, presumably owing to oedematous mucosa being sucked into and blocking the catheter orifices. During the next six hours 8 oz. of blood-stained urine drained through the catheters and a further considerable amount leaked around the catheters into the bed. On Oct. 19 5 oz. of slightly blood-stained urine was passed. On Oct. 20 vomiting ceased, and 110 oz. of clear urine was passed. Subsequently the patient recovered rapidly, and on discharge three weeks later had no symptoms and his urine was normal.

The highest blood urea recorded was 96 mg. per 100 c.cm. on Oct. 21, after which the figure gradually returned to normal.

Discussion

Incidence.—During the last six years one of us has treated the sulphonamide group of drugs, and particularly sulphapyridine, in about 4,000 cases. With the exception of the cases here reported all cases of haematuria have resolved on confinement to bed, cessation of the drug, large quantities of fluid by mouth, and enemata. The incidence is low, but likely to rise if the less-soluble sulphathiazole replaces sulphapyridine. According to Macartney *et al.* (1942) the rel

olubilities of acetyl sulphapyridine and acetyl sulphathiazole re 32.6 and 5.8 at pH 5.5, and 36.5 and 25.1 at pH 7.5.

Dosage.—In these two cases both the daily dose of 4 g. and the total amounts administered—9 and 13 g. respectively—are now to have brought about anuria, and suggest a personal diosynasy to the drug. The case reported by Laird had 1 g. four-hourly, with a total of 11 g.; the fatal case reported by Larson and Smith received 1 g. four-hourly, with a total of 2 g.; and the successful case reported by Benson and Percival received 21 g. in 3 days. These and other cases make it clear that without an adequate fluid intake anuria may occur with any therapeutically efficient dosage of sulphapyridine and alphanthiazole.

Diagnosis and Treatment.—The diagnosis is obvious, the early symptoms being haematuria, diminished secretion of urine, and pain in the loin which may radiate down to the groin, associated with persistent vomiting. If conservative treatment such as intravenous salines and large quantities of fluid by mouth does not relieve the symptoms quickly—say within six hours—it could seem wise to catheterize the ureters without delay. Such early treatment would appear to give the best chance of recovery and prevent permanent renal damage.

The cystoscopic appearances in Case II are similar to the necropsy findings reported by Carson and Smith, who also found the ureters blocked by crystalline debris. It seems probable in this case that when renal secretion was re-established secondary ureteric obstruction was avoided by the presence of ureteric catheters *in situ*. Having regard to the general condition of the patient, we have little doubt that in the absence of ureteric catheterization this case would have ended fatally.

Attention is drawn to two causes which may make the passage of ureteric catheters difficult or impossible—namely, crystals of the drug in the ureter, and the presence of a ureterocele. Case I demonstrated how rapidly ureterocele may progress, and seems likely that had the operation been delayed longer the passage of a ureteric catheter on either side would have been impossible.

Addendum

Since writing this paper one of us (A. G. J.) has had another case which supports the contention that early catheterization is the proper treatment of this condition—to secure drainage and to provide a method of washing out the renal pelvis, so as to prevent subsequent ureteric obstruction from blood and debris.

Briefly, the case history is that of a man aged 26 admitted to hospital with an acute epididymo-orchitis. A centrifuge deposit of urine showed pus cells in moderate number and a few organisms. Culture gave a growth of *B. coli*. He was nursed in bed, fluid intake was approximately six pints daily, and sulphapyridine 5 g. daily was given. On the third day, when a total of 15 g. of sulphapyridine had been taken, he passed deeply blood-stained urine, and complained of severe pain in and abdominal pain, with vomiting. Six hours later, as no urine had been passed, he was catheterized under a general anaesthetic, and intravenous fluids were started. The bladder was empty at otherwise normal, and catheters were passed easily up both ureters. Almost at once heavily blood-stained urine, containing crystals of sulphapyridine, was recovered from the left side. As there was no secretion from the right side 5 c.cm. of normal saline was injected into the renal pelvis, and secretion from this side was established some two hours later. Urine was passed round the catheters the next morning and they were removed. Subsequent progress was satisfactory, the urine being clear of blood on the fourth day.

Acknowledgments are due to the commanding officers of the military hospitals in which these patients were treated; also to Dr. Laurie, medical superintendent of Shroo Green Hospital, for permission to publish the third case.

IMMOBILIZATION AND TRANSPORTATION OF THE FRACTURED FEMUR IN WAR

BY

R. WOOD POWER, M.B., F.R.C.S.I.

Lieut.-Col., R.A.M.C.

The ideal method of transporting compound fractures of the femur from forward areas in warfare is undoubtedly the spica plaster. Trueta, following his experiences in the Spanish Civil War, has strongly advocated it. He and Böhler have pointed out the great importance of rest, not only for fractured bone but even more so for the lacerated muscles. They both agree that the most efficient splintage is the unpadded plaster spica. Trueta's method is undoubtedly ideal where distances are short, roads good, train transport luxurious and rapid, and the number of casualties small. In North Africa, however, where work at the field ambulances and C.C.S. has been heavy and quick evacuation imperative, where the roads are bad, and where single-track railways make evacuation slow, the spica plaster has not been found satisfactory. Here there are no ambulance trains *de luxe*, and patients evacuated to the base travel a distance of 400 miles or more on stretchers, on which the spica does not lie snugly. Bad roads or badly sprung railway trucks cause considerable shaking, resulting in friction sores on the buttocks, chest, or back. Similar conditions occur in sea transport: for the spica does not fit the cot, and the roll of the ship makes retention difficult and friction sores develop.

From the field ambulance or C.C.S. the wounded man is sent back to a forward hospital. Should complications arise or other wounds require treatment, he is retained there until fit to travel to the base hospital. This may be a period of many weeks, so the importance of correct fixation and alignment of the fracture is obvious.

Fractures of the femur have been evacuated to the base hospitals in North Africa by what is known as the "Tobruk" method, a description of which is as follows: When the toilet of the wound is completed a strapping extension is applied to each side of the limb, but circular strapping is not used for fear of subsequent swelling. A long plaster slab extending from the top of the thigh to the extremity of the toes is retained in position with circular plaster bandages. The tapes of the strapping emerge from the plaster above the ankle on either side, the plaster being cut around the points of exit. The plaster is split down the anterior aspect over a piece of rubber tubing which has previously been placed on the limb. A Thomas splint is fitted and the tapes protruding from the plaster are fastened to the end. Further circular plaster bandages from the thigh to the lower third of the leg keep the limb steady on the splint.

The "Tobruk" method is good for a short period, inasmuch as the patient travels in comparative comfort. Shortening, however, invariably occurs. This method is permissible for

the journey from a C.C.S. to a forward hospital, but if retained after a period of four or five days muscle spasm must be overcome by some means or other before full length can be obtained. The "Tobruk" method is mechanically unsound, for the plaster around the knee will counteract the pull of the strapping extension. Another cause of shortening is the failure to apply a perfectly fitting Thomas splint. The art of doing so appears to be dying out, especially among the younger generation of surgeons.

The ideal method of fixing these fractures (a) must ensure adequate fixation over a period of some weeks, (b) must entail the minimum of attention, and (c) must be easily transportable.

Method of Fixation

I have tried out a method in a forward hospital in North Africa which would appear to fulfil these requirements. It is

essentially the principle devised by Thomas and still practised by the Liverpool school. I have simply substituted an all-metal line of extension for the strapping. The latter requires constant daily attention, which it is impossible to give during transportation. Should the case be complicated by flesh wounds of the lower leg, strapping extension is altogether impossible.

The diagram of this method is self-explanatory. The pin and stirrup should be fitted under aseptic precautions before the surgeon deals with the wound. On completion of the operation, a thick posterior plaster slab is applied from below the knee to the extremity of the toes and retained in place with cotton bandage. The Thomas splint is applied, the surgeon seeing that it fits snugly round the thigh. While an assistant exerts traction on the stirrup the surgeon fastens it to the end of the splint by means of a piece of box wire, the ends of which should be left long.

The success of the method depends on the accurate fitting of the Thomas splint. If the ring is too small pressure will be borne on the upper thigh, leading to interference with the venous return. If the ring is too large pressure will occur on the anterior superior iliac spine, leading to an early pressure-sore, or else the ring will pass up into the folds of the buttock, interfering with defaecation or micturition. If the ring is too large it can be made to fit by padding the outer third with felt. If it is too small it can be divided on the posterior and inner aspect. It is important to bend the splint to an angle of 165 degrees at the knee-joint. If a straight splint is used the knee remains in full extension, which is uncomfortable and predisposes to backward bowing of the femur. Should full length of the limb not be obtained at the first fixation a lapse of four or five days will result in loss of muscle spasm, when the shortening can be overcome by application of a fresh wire. The ideal time for the application of this form of fixation is at the primary operation before muscle spasm has appeared. If extension is applied early there is no difficulty in procuring full length of the limb; the tendency would rather be to over-distract the fragments. This can be rectified later by slackening off the wire.

This mode of traction is ideal for fractures of the lower three-fourths of the femur and should produce perfect alignment. It is of course not suitable for fractures of the upper fourth where abduction of the proximal fragment occurs. It will, however, retain full length of the limb until the patient reaches the base hospital, where abduction treatment is facilitated.

Shortening of the limb must never be permitted in compound fractures, for it may lead to dire consequences. The first is mobility of the bone fragments. If this is allowed, muscle cells are repeatedly torn and die, thereby affording nourishment to the ever-lurking organism, which not only delays union and healing of the wound but may upset the delicate balance existing between the invading microbe and the natural resistances of the body. The second is the mobility allowed to the muscles. Lacerated muscles which are not kept at rest weep profusely, thereby causing loss of fluid from the body. The intermuscular septa open up when muscles are lax and form pockets in which pus will readily collect and track up the thigh. If the muscles are taut the intermuscular septa are closed and form a barrier to the extension of infection. The criterion of good surgery is the amount of discharge from the wound. If the wound has been well and properly saucerized, if bone fragments are in good position, and if muscles are taut and motionless, discharge will be at a minimum. If, on the other hand, the discharge is profuse we know that either the surgery or the fixation is at fault.

Advantages of the Method

The advantages of this form of immobilization over the "Tobruk" method are: (1) The whole limb is on view, so that gas gangrene or other infections can be detected early. (2) Re-dressing of the wound, if necessary, is simple. (3) Re-operation, if required, can be done with the splint *in situ*. (4) It is pre-eminently suitable if there are soft-tissue wounds of the leg. (5) Further manipulation and fixations are unnecessary, as shortening of the limb cannot occur. (6) There is no possibility of plaster sores or interference with the circulation. (7) Patients can be transported any distance, even by sea, with strict immobilization and the minimum of attention.

LOCAL CHEMOTHERAPY IN CHRONIC (NON-RHEUMATOID) RHEUMATISM

BY

G. LAUGHTON SCOTT, M.R.C.S.

Consultant in Rheumatic Diseases to the Almeric Paget Institute, Islington

Local chemotherapy denotes the therapeutic action of chemical substances so applied that immediate effect is confined to the area treated. It also suggests, if not implies, local bacteriostatic or bactericidal influence, which raises the objection that the existence of organisms in the rheumatic lesion is far from being proved. This is indeed a link missing in the chain of argument, but facts accumulate which seem to demand that hypothesis to explain them. At any rate, this sort of rationale is proposed for the present treatment.

Preliminary Diagnostic Investigation

It will be seen that a system founded upon the vital importance of the local rheumatic lesion requires the lesion to be defined with the greatest exactitude. Considerations of space prevent more than one example of how this need is met. In rheumatic sciatica diagnosis only begins with the discovery of signs, with errors of posture, and with the elimination of possibly non-rheumatic causes. It is when such matters have been finished with that location starts. The patient's pain may give direction if it is increased by coughing, sneezing, walking, sitting, bending the neck, or inclining the trunk towards or away from the affected side. Rectal examination will reveal tenderness of sacral roots or spasm of pyriformis; while the whole area must be searched for altered skin sensation. Guttman's (1940) colorimetric investigation of sweat secretion gives useful aid; but most important is the exploratory massage of lumbar, sacral, and gluteal regions, which discloses the various muscular lesions which may play their part in the syndrome. There is nothing new in such mapping of rheumatic geography except its thoroughness; and, indeed, ordinary physical treatment does not demand the same meticulous definition.

Composition of Injection and Method of Use

The trial of numerous essential oils over many years has not revealed the special power of any unusual medicament. The use of oil of niouli in osteo-arthritis was described (Scott 1938), and an oily suspension of streptococcal substance was successful (Scott, 1936a, 1936b); but no advance has been made upon a 10% solution of benzyl salicylate in oil. This is the mixture administered in the series described below.

Points of attack determined, the operator plans his dosage. Idiosyncrasy to the oil-soluble salicylate does not occur, though tolerance will vary. It will soon be seen that previous workers have failed of significant success because in fibrositis their dose was far too small, but in the treatment of joints much too large. In the former 20 c.cm., rising to 50 or 60 c.cm., is usually well tolerated; whereas with joints 0.1 c.cm. to 0.2 c.cm. must not be exceeded. Large injections are followed by malaise and pyrexia, but the effects soon pass. It is curious how closely the rules for vaccine administration govern the treatment—weekly spacing, rising doses, negative phase, and improving tolerance.

Results

Since 1932 about 1,500 patients have been dealt with, but some of earlier date are not now traceable, and, indeed, belong to a period when many problems of technique were fluid. A series of 96 recent and consecutive cases is therefore presented. All were treated over the past three years in a provincial town and have the corroboration of their doctor. A rigid standard of success has been applied, for "good result" is not claimed unless function, recovered on discharge, remains complete 1 date. Milder cases were rejected, as also all new cases of the rheumatoid type and osteo-arthritis of the hip, which do no benefit. Out of the 96 cases, 76 results are returned as good, 14 as fair, and 6 as failures. Twelve cases, the most severe are described below in some detail; with these contact has been maintained so that points of interest may be verified.

LOCAL CHEMOTHERAPY IN CHRONIC RHEUMATISM

Illustrative Cases

Case 1, Fibrositis.—Masseuse aged 47; 15 years' fibrositis neck, shoulders, back, buttocks—much physiotherapy; feared retirement. Six treatments—severe reactions. Two months later little signs left; confirmed by another masseuse; "better than for years." July 20, 1943 (9 months after): full practice; well. Result: (a) function normal; (b) pain trifling.

Case 2, Fibrositis.—Architect aged 58; brother, father, grandfather, and great-grandfather disabled from walking at 55. Last named lifted into coach by crane! No gout; blood uric acid twice low; radiographs showed no changes. Fibrositis of plantares marked—lower os calcis acutely tender—short extensors fibrositic; impaired movement toes; tendo Achillis thickened; fibrositis in soleus, peronei. Symptoms in 1932: for year walking 5 miles, multiple injections over 4 weeks. In six weeks walking 5 miles, painless; day's shooting. Well 9 months later. Result: (a) function normal; (b) pain nil.

Case 3, Fibrositis.—Broker aged 59, once first-class tennis player. April 12, 1943, reported 3½ years' disablement—neck, shoulders, knees, feet; "can't climb stile or lift hoe." Rheumatologist had not helped. Cold swollen hands, staggering walk, rheumatoid appearance. Three examinations, with masseur; found fibrositis in neck, sacro-iliac, sciatic notch; crippled state did not seem accounted for. One treatment; 120 c.cm. standard mixture. Left 11th day, walking freely. May 15, 1943: nothing abnormal; hardest labour on farm. Well since. Such quick recovery rare; needed location of all lesions—seldom made at outset. Result: (a) function normal; (b) pain nil.

Case 4, Osteo-arthritis of Spine, etc.; Fibrositis.—Solicitor aged 68, seen Sept. 11, 1940; imprisoned in heavy steel jacket since 1922. X-ray report (1929): "Marked osteo-arthritis of spine, chiefly D 8 to 12; all lumbar vertebrae affected; osteo-arthritis of knees and great toes; severe sacro-iliac arthritis." Yearly visits to Aix-les-Bains 6 times. Cervical, lumbar, gluteal, and sacro-iliac fibrositis, which was attacked; after 8 treatments pain absent. Soon laborious work in garden, sometimes walked 5 miles. With vious of entirely discarding jacket, but year later had done so. Provides example that rare single treatments, well in all respects. Provides example that severe spinal osteo-arthritis may cease to disable if accompanying fibrositis is successfully treated. Result: (a) function normal for age; (b) pain rare.

Case 5, Osteo-arthritis of Knees, Wrists.—Clerk aged 66; arthritis of knees for years. Gross bony changes; any walking impossible; despair at losing work. Both knees hot, very swollen: flexion of R. knee limited. Progress slow, minimal dosage. After six weeks walked a mile—soon two miles. Returned to work 8 weeks after starting treatment. Later, wrists treated. X-ray report (Schwartzman): "In P.A. position, blurring of metacarpal bones; marked lipping seen in lateral position—marked hypertrophic osteo-arthritis." After 7 treatments heat and swelling gone. Function much improved. Result: (a) function normal, (b) pain slight; nil; wrists—(a) function much improved, (b) pain slight.

Case 6, Osteo-arthritis of Knees.—Married woman aged 66, "incapacitated in knees" 2 years before. Noted orthopaedist July 30, 1941: "X rays show marked degree of osteo-arthritis in both knees—proliferation round joint margins—elongation of tibial spines; further treatment was useless." Walked little and painfully for 18 months. Result: (a) function normal; (b) pain nil.

Case 7, Osteo-arthritis of Knees.—Ex-Army man aged 73; "many accidents to knees earlier"; 10 years' poor walking; 1 year hardly walked at all. Knees hot, tender, swollen. X-ray report, Oct. 5, 1940 (Shanks): "Gross chronic osteo-arthritis changes in both knees—large osteophytes; some detached and may be loose in knee." 11 injections after 1941; painless function; several miles daily. Further injections to ascertain whether changes seen by x rays could be modified. Not the case. Interest lies in recovery of function after almost maximal disorganization. Remains well. Result: (a) function normal for age; (b) pain nil.

Case 8, Osteo-arthritis of Knee.—Theatrical producer aged 42; injury to foot as boy—amputation of toe; cartilage removed. For years pain on exercise; recently splinted, confined bed, where examined July 27, 1942. X-ray report (Schwartzman): "Tubercle of L. knee enlarged; joint space narrowed; border of patella pointed; some lipping lower femur." Head of fibula enlarged by osteophytes; operation suggested. Moderate walking in 4 weeks; since then, with few single treatments, walks without limitation. Result: (a) function normal; (b) pain rare and slight.

Case 9, Polyarthritis.—Sawyer aged 62, Jan. 5, 1943: Active process in wrists, elbows, shoulders, knees, ankles; symptoms for years; employer anxious lest he must be retired. No radiographs. Soon improvement despite heavy labour. 7 sessions; pain slight. March 1: no abnormality except wrists; puffy, not painful.

Employer writes: "Sings instead of cries on way home." Well since. Result: (a) function normal; (b) pain greatly reduced.

Case 10, Rheumatic Sciatica.—Stonemason aged 37; sciatica years before; recurrence 9 months ago—long hospital treatment—advised permanent light work—incapacitated. April 23, 1941: Lasègue +; wasted L. buttock; A.-J.s equal; sensory loss outer leg, sole. Per rectum, pyriformis spasm; tender sacral roots. Six treatments—no better. June 17, 1941: only pain over S 1, 2; now left A.-J. depressed. Posterior sacral foramina 1, 2, 3 injected—benefit; reinjected—pain gone. Heavy work soon after; active to date. Result: (a) function normal; (b) pain nil.

Case 11, "Sciatica."—Typist aged 20; acute symptoms 20 weeks; 6 weeks bed, then bath-chair. Consultations at local hospital indecisive. Sept. 7, 1942: contralateral scoliosis; Lasègue +; A.-J.s equal; sensory loss sole; per rectum, nil; tender over S 2, nowhere else. Involvement of S 2 diagnosed in spite of equal A.-J.s. Injection posterior sacral foramina—pain gone. A few gluteal injections; Well and active since Oct. 30, 1942. Result: (a) function normal; (b) pain nil.

Case 12, Rheumatic Sciatica.—Surgeon aged 48, seen Dec. 10, 1942, 3 years previously treated for months in London home by 5 physicians; one, expert in injections, gave 20 treatments. Unimproved; eventually to work, but even with analgesics uncomfortable. Nov. 1942: acute recurrence; Lasègue and Mennell +; gluteal atrophy; per rectum, S 2, 3 tender; pyriformis spasm. Sensory loss indicated L 5, S 1, 2, 3. No A.-J. Treatment for 5 weeks; 7th week, symptomless, walking freely, A.-J. still absent. Well since; recent fracture of pelvis caused no relapse. Result: (a) function normal; (b) pain nil.

Claim of Innovation

The common criticism of all new work is that it is not new at all. Certainly the chemical substances used by me are not new, and in oil-soluble form they are not untried. Claim to novelty fails if there is no more in it than this. But there is more; there is the contention that when they are properly applied the oily salicylates are specific in chronic rheumatism; furthermore, it is maintained that this fact has escaped previous workers because their dosage was wrong and their technique imperfect. If items of intra-articular recorded spell the difference between success and failure, then technical improvement constitutes innovation. In many respects this can be shown to be true. The literature of Forestier's chemotherapy, for example, hardly exists except for Forestier's scanty notes, yet the need for extremely minute doses can be shown to be so obvious that it must have been recorded if observed. With correct dosage the prognosis of the rheumatic joint is transformed. When first, in 1932, I attempted intra-articular injection a doubtful result after much reactional pain was the rule. Now there is no pain—not even interruption of normal activity—and results are remarkable.

But optimal dosage has proved simpler to work out than many essential details of technique. In neuritis local injection will not do much if it has no more than anatomy to guide it. This is particularly true of brachial neuritis, which is often cured in one or two sessions when injection is made over the intervertebral foramina. In rheumatic sciatica six areas need to be explored as possibly contributing to that composite entity. Such details are few among many that deserve, but have yet to receive, description. Nor is there mention of the systemic benefit which often follows local chemotherapy. That local treatment should profoundly affect the general health requires proof and modification of accepted theories. But such considerations are outside the practical issues here put forward.

Summary

It is suggested that local chemotherapy has notable possibilities in the treatment of chronic rheumatism. Emphasis is laid on the need for extreme accuracy in locating the rheumatic lesion before it is attacked; some account of the application of the method is given. The results obtained in a series of 96 consecutive and fully corroborated cases are assessed; 12 of these are briefly described. The claim to innovation rests upon matters of dosage and technique, the past neglect of which has obscured the value of local chemotherapy in chronic rheumatism.

A CASE OF CONGENITAL DILATATION OF THE PULMONARY ARTERY

BY

H. L. HEIMANN, M.D., M.R.C.P.

Lieut.-Col., S.A.M.C.

AND

M. M. POSEL, M.D., M.R.C.P.

Major, S.A.M.C.

(From Oribi Military Hospital, Pietermaritzburg, Natal)

(WITH PHOTOGRAPHURE PLATE)

According to Bedford, Paff, and Parkinson (1941) congenital dilatation of the pulmonary artery is a rarity, while septal defect is the commonest congenital malformation of the heart. Those authors stress the great dilatation of the pulmonary artery and its branches that accompanies atrial septal defect, and, while attempting to differentiate between these two conditions, confess that differential diagnosis may be impossible. Other authors, notably Assmann (1928), describe this congenital dilatation as a primary condition due to asymmetrical divisions of the truncus arteriosus communis.

Jennes (1936) points out that dilatation of the pulmonary artery is as rare as dilatation of the aorta is common. In a total of 38,000 necropsies done at various English-speaking hospitals no case was discovered up to 1936. In all, 122 cases have been recognized, and, with the exception of 12, all at necropsy. From the descriptions of some of these cases they were probably of the type described by Bedford, Paff, and Parkinson. Master (1939) states that in atrial septal defect large auricles result, with enormous P waves. The opinion expressed by Bedford, Paff, and Parkinson (1941) is contrary to this statement: except in a certain proportion of cases, the right auricle was grossly enlarged, but not the left.

Assmann's classification of congenital dilatation of the pulmonary artery appears to be of value, and is as follows:

A. Acquired :

- (1) Aneurysm of the pulmonary artery
- (2) Perforation of aneurysm of aorta into pulmonary artery
- (3) Pulmonary insufficiency from endocarditis
- (4) Stasis in pulmonary circulation, as in mitral stenosis

B. Congenital :

- (1) Solitary single anomaly (asymmetrical division of truncus arteriosus communis)
- (2) Open ductus botalli
- (3) Pulmonary stenosis (very exceptional)
- (4) Defect of auricular septum
- (5) Defect of ventricular septum

Radiology plays an important part in the diagnosis of this condition, and the criteria of x-ray diagnosis seem to be as follows:

- (1) Increase of pulmonary bow
- (2) Small aortic knuckle
- (3) Broadening of hilar shadows
- (4) Enlargement of the pulmonary arterial tree. The oblique positions, together with the barium swallow, will show the characteristic picture of the enlarged pulmonary artery.

In view of the rarity of the condition, we are adding a description of a case which conforms, radiologically and otherwise, to those already described.

Clinical History

The patient, a man aged 23, was admitted to hospital because of "feverishness" and pains in the joints. Influenza was diagnosed, but routine examination revealed certain peculiar features. He was 6 ft. 5½ in. in height, and had clubbed fingers and a very blue tinge on his lips. At the age of 10 he had been told that he had "something wrong" with his heart, but this had not precluded him from having a fairly normal adolescence. He had played games at school, but could not run fast. He had had no illnesses and had lost no schooling. Three years previously he had coughed up a cupful of blood, but his doctor told him it was due to "lung strain." He had had no chest pains, cough, or expectoration. Neither had he had any sore throats, joint pains, or any kind of body rash.

The family history was not relevant, except that his father was a very tall man of 6 ft. 5 in., and his sister was also over 6 ft. The head and neck showed no abnormality. The apex beat was well out, five inches from the mid-sternal line. There was a palpable thrill, diastolic in time, over the præcordium—not like the systolic thrill of mitral stenosis, but sharp and abrupt. On auscultation there was a mid-diastolic murmur, heard at the apex and conducted out. There were no moist sounds in the lungs. The pulmonary and aortic areas were clear. The liver was not palpable. The blood pressure was 140/70. The Wassermann reaction was negative, and the blood count showed 7,500,000 red cells, Hb 64% (Sahli), and a white cell count of 13,000.

The electrocardiogram did not show a right axis deviation measurement on the Einthoven triangle. There were inverted waves of the coronary type, with depression of the S-T segment below the isoelectric line, in both arm and leg apex leads taken in the conventional manner. The three limb leads showed diaphanous QRS complexes suggestive of congenital heart disease as described by Katz.

X-ray examination demonstrated a huge pulmonary artery in a comma-shaped branch, also greatly enlarged in the antero-posterior position (Plate, Fig. 1). After a barium swallow a very large impression made by the right pulmonary artery in the right oblique position was a striking feature (Fig. 2).

We conclude that the above is a case of congenital dilatation of the pulmonary artery and its branches. Atrial septal defect might be present, but this is uncertain, as the right auricle was not grossly enlarged.

Medical Memoranda

A Case of Traumatic Ventricular Pneumocephalus

(WITH PHOTOGRAPHURE PLATE)

Cases of traumatic ventricular pneumocephalus reported in the literature are few in number, and Davies (1943), who described one case of his own, could find only about twelve in the British literature. It may therefore be of value to put on record another instance of this rare condition.

HISTORY OF CASE

A man aged 33 was found lying alongside a road late at night and was admitted to the Staffordshire General Infirmary on May 1943, in a deeply comatose condition. The exact nature of the accident could not be ascertained, but from the time factors it was judged that he had been lying out in the cold at least one hour. On examination a small puncture wound, quarter of an inch in diameter, was found over the left eye, fairly large abrasions of the forehead and just below the canthus of the left eye. The eyelids on both sides were very swollen and could be opened only with difficulty, but enough to show subconjunctival haemorrhage in the left eye. There was no bleeding from ears or nose, nor was any other injury found. His temperature was subnormal, but the pulse was fairly strong, with a rate of 60 a minute. Fracture of the skull was diagnosed; the patient was admitted and treated for shock. Because of his general condition surgical toilet was not performed.

By the following morning he had passed into a state of cerebral irritation, and this irritation alternated with long periods of coma. Dehydration treatment was begun, using a 50% solution of sodium sulphate, 4 oz. six-hourly, per rectum. By the next day he was completely conscious, and complained of pain in the occipital region. This pain later shifted to the left temporal area, and during his stay in hospital he had repeated attacks of pain in this region.

On the fourth day after admission the patient complained of stiffness of his neck. Examination showed physical signs of meningitis, although temperature and pulse were normal. Lumbar puncture the cerebrospinal fluid was found to be of normal pressure and fairly heavily blood-stained. This fluid contained no coagulum, and the supernatant fluid was faintly yellow. Numerous red blood cells were present, but there was no incursion of leucocytes, and films showed only Gram-positive bacilli. On culture, only aerial contaminants were found. The dehydration treatment was stopped and the patient put on a course of salicylates, and the meningitic symptoms passed off in a few days.

Apart from the continued headaches, for which phenobarbital was given, the patient made good progress until June 2, when

veloped a left-sided supranuclear facial paralysis. The following day the patient was radiographed for the first time, when a massive comminuted fracture extending nearly round the calvarium was found. There was no involvement of the base of the skull, but the x-ray film showed perfect outlines of the third and lateral ventricles due to the air in them (see Figs. 1 and 2 on Plate). Another radiograph was taken on June 19; this showed that the air had been absorbed.

About June 25 the patient developed diplopia of the left eye with ectropion of the lower eyelid. The ectropion was due to carrying of an abrasion below the lid; and scarring inside the orbit affecting the external rectus would account for the diplopia, since no injury to the sixth cranial nerve could be found.

The patient made good progress and was discharged after seven weeks in hospital. When seen on July 21 he was complaining of complete deafness in the left ear. The facial paralysis was beginning to pass off, and cutaneous sensation was present on the left side of the face. A radiograph taken in Towne's position showed a fracture extending into the petrous portion of the temporal bone, which would account for the seventh and eighth cranial nerves being affected. The probable route of entry of the air was through either the frontal wound or the ear and then by a dural tear into the subarachnoid space. The air would then rise in the ventricular system to the third and lateral ventricles.

My thanks are due to Mr. G. I. Wilson for his encouragement and advice, and for permission to publish this case.

M. GANES, L.R.C.P.S. Ed.,
House-surgeon, Staffordshire General Infirmary.

Generalized Sensitivity to Sulphonamides

The recent article by Major Park (*Journal*, July 17, p. 69) has drawn attention to a condition of increasing incidence which is at present by no means always recognized. I am therefore prompted to quote the following case of cutaneous hypersensitivity to sulphanilamide powder applied to an extremely minute lesion. This was to the site of a small penile wart which had been cauterized.

CASE HISTORY

The patient was a soldier, aged 23, of 3½ years' service; previous occupation, plumber. He had been in hospital for 4 to 5 days a year ago with a rash the details of which I have been unable to obtain. He had never previously taken any sulphonamides.

In March, 1943, he had two small penile warts removed by cauterization, and sulphanilamide powder was applied. He attended a week later, and, as the warts had not disappeared, the process of cautery and powder was repeated, as it was also on the occasion of his next visit, a week after this. He powdered the wart sites three times daily at his unit during this period. The two areas in question were only about 2 to 3 mm. square. At his next attendance, a week later, the warts had gone but the small sites were still unhealed. More powder was given, as was done under similar circumstances at the end of the fourth week. After applying sulphanilamide powder thus for one month to this almost insignificant lesion, his penis swelled up, and he developed a rash on that organ, extensor surface of arms, and face. This was not seen personally, as he was treated at his unit. The rash subsided in a few days with calamine lotion to face and arms and vaseline to the penis. The wart site healed, and he went on leave to arrange for his forthcoming marriage.

Two weeks later the wart, however, recurred and he attended hospital again on May 8. He saw a different medical officer, and volunteered no information concerning his skin trouble. The wart was treated as before with cautery and sulphanilamide powder, and he was detained in hospital to settle finally with it. On May 10 there was some oedema of the prepuce with commencing eczematization. The condition was recognized and saline washes were given. On May 11 he also had dermatitis on face, both forearms, and hands, with an erythematous eruption on chest and legs. This settled well by May 18, and his contumacious wart was once more treated—this time by lig. epispasticus and starch and boric powder—and he was discharged from hospital on May 25. He was seen again on June 2, and on June 9 was detained for a patch test. This test was done on lint moistened in axillary sweat, pieces of which, powdered with sulphapyridine, sulphathiazole, sulphadiazine, sulphamethazine, sulphanyl-mandelate, and sulphanilamide respectively, were strapped to the unbroken skin on the back for 24 hours. No action occurred from any of these.

I was tempted to carry out scratch tests and to give him tablets by mouth to see the reaction, but as at long last he was in a fit state to be married after some trying weeks of frustration, he was discharged.

CONCLUSIONS

Obviously sulphanilamide powder should not be applied to even insignificant lesions for such a lengthy period as above. The fact that a lesion is not healed under sulphanilamide powder within a week should be evidence that it does not suit and that a local or a generalized dermatitis is likely.

Reviews

CHAOS IN THE MEDICAL SERVICES

The Future of Medicine. By D. Stark Murray, B.Sc., M.B., Ch.B. (pp. 125. 9d.) West Drayton: Penguin Books Ltd.

This addition to the "Penguin Specials" can be cordially recommended. It is packed with interesting information clearly presented. Some of the chapters—e.g., 6 and 7, "Could Medicine Do More?" and "The Chaos which is Medicine To-day"—I found particularly stimulating. The patchwork nature of the medical services of this country has long been a byword among those who have studied it, and Dr. Stark Murray manages to deal not only concisely but vividly with a subject which might have been thought threadbare. The ingenious diagram on page 76, showing "how a family gets its medical service to-day," may be regarded by the reader as either a comedy (of errors!) or a tragedy—depending on one's mood. But though I approve Dr. Murray's diagnosis, I cannot agree with his suggested treatment. While we are all in favour of making it as easy as possible for everybody to get the medical services he requires, it is evident that there is room for honest difference of opinion as to how this is to be done. Dr. Murray is an out-and-out supporter of a whole-time salaried service. For this there is a good case if one is content to adopt the somewhat inhuman attitude of the convinced Socialist, who seems to ignore the individual in his concern for the "community." This is well illustrated by the author's approval of a scornful reference to the "wastefulness" of the visits of several doctors to patients in the same street. This may be called "wasteful" if we ignore the legitimate desires of the average man and woman, but some of us have not yet attained this attitude of superiority to human weakness. I would advise Dr. Murray to try on some of his Socialist friends, ordinary common people, say in Lancashire or Yorkshire, his dislike of this form of "wastefulness"; or perhaps he might vary it by suggesting that it is "wasteful" for a woman to prefer to spread her purchases over various shops, according to her fancies, instead of buying everything at one store. I must confess to a strong dislike for the prospect of a world in which everything, including human nature, is to be planned and managed and levelled out.

There are a few points of detail to which attention may be called. The only factual error I have detected is on page 63, where the author says "there is no longer any restriction of any kind on the sale of patent and proprietary remedies." This overlooks the Pharmacy and Medicines Act of 1941, which puts many restrictions on their sale, and insists, for example, on the publication of their formulae. It was rather surprising to find on page 42 that Dr. Murray says that the patient in a public hospital is "more likely to be treated as a human being than in a voluntary hospital." I should very much doubt this. In his chapter on "The Specialist," which I can heartily commend, Dr. Murray says that it is difficult to define a "consultant." Surely a real "consultant" is one whose opinion is valued by his peers. On page 78 the author says that the "panel patient's wife in a very large proportion of cases calls in her own private doctor, a quite different person." This does not agree with what I have been told by many general practitioners.

I hope this little book will have a wide circulation; that its diagnosis of the chaotic position of the medical services of this country will be pondered by many who have not thought about it; but that its prescription for the cure of the disease may be very carefully measured by a reference to what the reader would desire for himself. Men and women have little use for the "community" when they are sick, and the main use of medical services for most of us must continue for a long time to be when we are sick. Whatever changes we make—and Dr. Murray convincingly shows that many are overdue—we must not mechanize and dehumanize the relations between patient and doctor.

ALFRED COX.

ANATOMY OF THE FEMALE PELVIS

The Anatomy of the Female Pelvis: Including a Description of the Placenta and its Formation and the Foetal Circulation. By C. F. V. Smout, M.B., Ch.B. With sections, in Part I, on the Histology of the Female Reproductive Tract and a chapter on Ovarian Endocrine Function by F. Jacoby, M.D. Foreword by Sir Beckwith Whitehouse, F.R.C.S., F.R.C.O.G. (Pp. 190. 35s.) London: Edward Arnold and Co.

Dr. Smout has compiled a neat but comprehensive monograph on the anatomy of the female pelvis. By his handling of the subject and by the inclusion of sections written by Dr. F. Jacoby on the histology of the female reproductive tract and ovarian endocrine function he has done more than write an anatomical study: he has written a volume of great interest to the clinician as well as to the preclinical student. The expressed wish that portions of the book may be useful in the training of midwives is a reasonable one, and it is to be hoped that those responsible for their teaching will not overlook its merits. If one admits that histology should be taught with anatomy (and we do), then the book is arranged on orthodox lines. The study is developed from an osteological basis, with chapters dealing with the bones, the joints, the walls, the fascia, and the contents of the female pelvis. The last few pages are devoted to the foetal circulation and placenta formation.

The work has been most carefully prepared and is beautifully illustrated, but none the less there is something not quite satisfying about it so far as its clinical applications are concerned. The anatomy of the pelvis is of the greatest interest and significance to the obstetrical and gynaecological operator, and if a monograph on the subject is to be of much practical use to him it must be accurate and it should give some reference to the more serious variations of the normal with which he will have to deal. It might also be argued with reason that the anatomy of the more important surgical approaches could be discussed. For example, the ureter is for the gynaecologist one of the most important structures in the pelvis, and he must be acquainted with its whereabouts when he operates both per abdomen and per vaginam. Yet the ureter is discussed in a few lines: nothing is said of its anatomical variations, of its displacement by tumours or prolapse, and little space is devoted to the detailed anatomy of its relation to the vaginal vault, cervix, and uterine vessels. Knowledge of these points is essential to the safe performance of a radical hysterectomy, but the operator would find little in this monograph to help him in this respect. The uterine artery is described as arising from the internal iliac, and an excellent illustration is given of this; but no reference is made to its origin from the unobliterated part of the obliterated hypogastric vessel, though it would be fair to say that this is more often its origin than the one described. Proof of this fact, which is known to any experienced operator in the pelvis, can be found in the excellent records given by Bonney of his numerous pelvic dissections in his series of Wertheim operations. These are the points on which the value of a monograph such as this must ultimately be judged if it is to be accepted as a guide to sound practice.

SURGERY FOR THE SERVICE M.O.

A Pocket Surgery. By Philip H. Mitchiner, C.B.E., M.S., F.R.C.S., and A. Hedley Whyte, M.B., M.S., F.R.C.S. (Pp. 272. 10s. 6d.) London: J. and A. Churchill, 1943.

The authors' declared object is the production of a concise account of the diagnosis and treatment of injuries and surgical diseases with which medical officers in the Services are constantly in contact. The results of treatment are not discussed. Beginning with a section on the principles of war surgery, they then deal by systems with injuries and diseases of various organs, and in this respect acknowledge that the plan of the book follows the larger textbook on the *Science and Practice of Surgery* by Romanis and Mitchiner. The book is dedicated to H.R.H. the Princess Royal. A great deal is compressed into its small size, and it is inevitable, therefore, that detail suffers to a certain extent in consequence, and some statements are consequently not very helpful and may even be misleading—e.g., p. 104: "Measurement of fluid pressure is of value in cases of spinal tumour (the basis of Queckenstedt's test)." It is the shape of the wave produced by jugular compression that constitutes this test and not any primary measurement of cerebrospinal fluid pressure. Despite the well-known views of one of the authors, we are glad to note that they

advise radical amputation for carcinoma of the breast, but we would question the advisability of treating duct papilloma with x rays or radium needles applied around the nipple (p. 175). We do not agree with the advice given for finger amputation (p. 100)—"metacarpal" in this paragraph is obviously a misprint for "phalangeal." Whether Service medical officers are likely to be in constant contact with Hirschsprung's disease (p. 205) and haematocolpos (p. 252), to take only a couple of the many conditions in the wide field over which the author skims, is perhaps questionable, but the book should prove a useful little manual for a general revision course, even more perhaps, to the elderly Regular officer than the more recent qualified younger man. There are no illustrations except a stylized plate showing amputation sites and abdominal incisions; but the printing is good and the type easily read, and an index adds to the value of a manual which will fit comfortably in the tunic pocket.

Notes on Books

Dr. WILFRID SHELTON has undertaken an extensive revision of a popular textbook *Diseases of Infancy and Childhood* for a new edition and it remains one of the soundest and most comprehensive volumes for its size on this increasingly important subject. Some more extensive sections on the psychological problems of childhood would improve its usefulness, for there is little indication for the management of the various behaviour problems that are likely to be brought to a practitioner for help. Many of the recent advances in medicine have a direct usefulness in paediatrics, and Dr. Sheldon shows by his footnotes that he keeps well in touch with modern developments. No doubt he will in a future edition modify his statements on the pathology of catarrhal jaundice, for which he still favours the theory of ascending cholangitis. The volume is well illustrated and attractively set out. Its popularity is shown by the appearance of a fourth edition within nine years of the first, and this revision will undoubtedly gain many fresh readers. The publishers are J. and A. Churchill and the price is 28s.

The valuable pamphlet entitled *Diabetes in Wartime*, prepared for patients attending the Diabetic Clinic at University College Hospital, London, has now been republished in a second edition by H. K. Lewis and Co., at 1s. The instructions on the diets and their alternations are as clear as before, and the dietaries are fitted to wartime conditions.

William Heinemann (Medical Books) Ltd. will be issuing December at 30s. *The Inner Ear*, by J. Fischer and L. E. Wolf (Grune and Stratton, New York), which was reviewed in our issue of Oct. 2.

Preparations and Appliances

A SULPHONAMIDE POWDER SPRAY

Air Commodore STANFORD CADE, F.R.C.S., writes:

The local application of sulphonamides to wounds creates a demand for an instrument more accurate than the pepper-sprayer. The usual insufflators were found to be unsuitable as the powder either clogged or was delivered in largish quantities. In 1941, the insufflator here illustrated was made for me by Donald Rose. Its special points are as follows:

It is made entirely of metal; there are no rubber washers; the metal base is heavy, so that the instrument does not wobble; the nozzle is detachable. The powder passes up inside the container along a hollow narrow metal tube into a flat box fitted into the upper compartment, which is the lid of the insufflator. The floor of this box is provided with a hole bigger in diameter than the tube along which the powder is ejected. Gentle pressure on the rubber bulb gives a fine intermittent spray of powder so that thin frosting of wound is obtained, the bulk of the powder returning to the container through the hole in the floor of the box. The length of the nozzle enables the depths of the wound to be reached. The metal part is easily sterilized by dry heat in an autoclave. This insufflator has been supplied to all R.A.F. hospitals and station sick quarters, both at home and overseas. It proved very useful, and the past two years' experience well encourages me to publish this note. It can be obtained from Donald Rose, 36, George Street, W.1.

INDUSTRIAL LEAD POISONING

The outstanding feature in the history of the campaign against lead poisoning in this country is its successful outcome. Though cases of lead poisoning do still occur—there was one fatal case of lead encephalopathy in the ship-breaking industry in 1942—their incidence has shown a steady fall during the last three decades. The number of cases notified in 1913, for example (not including those that occurred in the painting of buildings), was 535; in 1942 the number was 66. Cases from painting of buildings became notifiable only in 1927: in that year the incidence was 98; in 1942 it was 6. It was in 1927 that the controversy on the prohibition of the use of white lead for painting the interior of buildings ended in the passing of the Lead Paint (Protection against Poisoning) Act, which forbade dry rubbing down for the removal of old paint. There can be no doubt that this prohibition has been one of the most effective measures of control of the lead hazard, since the most important single factor in lead poisoning is the inhalation of dust or fume containing lead. Classes of industry in which this hazard predominantly occurs are ship-breaking, where fumes are given off from the lead-painted plates under the blow-pipe flame, and dust and fume from the chipping and burning of lead paint; and the manufacture of red and white lead. A peak in the incidence curve in 1924 (486 cases notified) was chiefly due to the post-war increase in ship-breaking. Another, in 1934 (157 cases notified), was associated with an increase in the manufacture of electrical accumulators, where dust and fume arise during many stages of the process. But in this industry, as in other processes of high potential risk, such as the pottery industry, smelting of metals, plumbing and soldering, vitreous enamelling, shipbuilding, etc., the number of cases of lead poisoning has shown a steady decline.

This improvement can be attributed first to protective measures, such as the suppression of dust, under the prohibition by the Lead Paint Regulations of 1927 of the use of lead paint in the form of spray in interior painting; the damping or wetting of floors and material, as required by the Regulations for Smelting of Materials containing Lead; the removal of dust by locally applied exhaust ventilation, etc. A second factor is the improved personal hygiene of the worker, and exclusion of women and children from specially dangerous processes. Thirdly, there has been earlier recognition of the disease, helped by compulsory periodical medical examination of the workers and by improved methods of diagnosis. Those who use the most recent aids to diagnosis, however, involving scientific procedures of a high level of accuracy, stress the fact that either singly or in combination they are aids only, and must be considered strictly in relation to the clinical signs and symptoms of lead poisoning. The measurement of lead exposure by analysis of the lead content of the atmosphere, for instance, can and does determine whether the threshold generally considered¹ that of dangerous exposure to lead—1.5 mg. of lead per 10 cu. m. of air—is being exceeded, but it cannot determine the amount of disability in a case of lead poisoning or estab-

lish the diagnosis in a particular individual. Similarly, analyses of the lead content of the blood, urine, and faeces of exposed persons must take into consideration many other factors, including the variability of these figures in normal or unexposed individuals. The "normal" average concentrations are 0.03 mg. per 100 g. of blood, 0.027 mg. per litre of urine, and 0.27 mg. per 24-hour faecal sample.² A series of investigations on workers exposed to lead has revealed a definite trend towards a rise in these concentrations as the severity of exposure increases. The urinary and blood findings are more constant than the faecal, and provide a better criterion, especially under conditions of exposure to fume. A marked rise in the faecal lead is usually found only in industries associated with lead dust, which finds its way chiefly into the faeces. Typical figures for a group of operatives engaged, with known severe exposure, in the manufacture of white lead are: blood, 0.086 per 100 g.; urine, 0.336 mg. per litre; faeces, 7.6 mg. per 24-hour sample. But, as in the case of air analyses, these figures should be used as an indication of the severity and character of the exposure rather than as a diagnostic criterion of lead poisoning.

With regard to the oldest diagnostic aid, punctate basophilia, the early hopes of its specificity as a sign of either lead intoxication or lead absorption have faded, especially as to a quantitative correlation between numbers of stippled cells, amount of lead absorbed, and severity of exposure. Stippled cells occur not only in blood dyscrasias from causes other than lead but also in healthy persons without occupational exposure to lead. Conversely, the frequency of stippled cells in the blood of a group of workmen with a proved lead exposure and with significant quantities of lead in the urine has been found³ to be no greater than that of a "normal" group. Nor is the size of the basophilic granules to be regarded as strictly related to the stimulus of lead itself, but to the large numbers of cells produced by any stimulus. Positive results are diagnostic in the individual in high numbers only—more than 9,000 stippled cells per million. Average group findings in excess of 1,000 per million, in the absence of other known causes, suggest increased lead absorption.

The clinical picture of lead poisoning still retains its classical outline, but with the distinction between lead poisoning and lead absorption more sharply drawn. The most serious manifestation of acute lead poisoning is, of course, lead encephalopathy, which differs in no way in the adult from any other form of cerebral irritation, and the diagnosis of which needs all the help of laboratory methods and occupational history. A less acute form, characterized by constipation antedating severe colic, sometimes accompanied by diarrhoea, headache, and vertigo, may develop gradually from a condition of general weakness and lassitude, loss of weight, and aching of the joints, or may make an abrupt entrance after a short period of severe exposure. The familiar "dropped wrist" is usually a late manifestation of chronic poisoning; other muscles, depending to some extent on the strain to which they are subjected, may be involved. "Blue line" on the gums, due to the local deposition of black sulphide of lead, is not evidence of lead poisoning but only of severe exposure. It is never found in the absence of teeth or in a completely clean and healthy mouth.

In fact, neither symptoms, nor physical signs, nor laboratory findings can singly give a clear line of differentiation between lead poisoning and lead absorption. "The medical diagnosis represents an opinion: the facts consist of the objective findings and the corroborative evidence supplied by the laboratory."

THE PUBLIC HEALTH: CONTRADICTIONARY SIGNPOSTS

The paradox of public health in wartime whereby the vital statistics are better than in the years of peace and yet a great increase in minor illness is reported is examined at some length in the Summary Report of the Ministry of Health.¹ The favourable records in the vital statistics are certainly remarkable. In 1942 the standardized death rate among civilians in England and Wales was the lowest ever recorded. It was the lowest alike for males and for females, though large numbers of healthy young people, especially males, had been withdrawn from the civilian population. Maternal and infant death rates were also at their lowest, infant mortality for the first time falling below 50 per 1,000 births. New low records were established in the mortality from pneumonia, diphtheria, scarlet fever, rheumatic fever, chronic endocarditis and valvular disease, gall-bladder diseases, post-syphilitic disease, and gastric ulcer and other diseases of the stomach. Alcoholism and cirrhosis of the liver took a lessened toll. The deaths from influenza were less than half the number recorded in 1941. The total incidence of infectious diseases was probably lower than ever before, though changes in notification make comparisons difficult. The figures for diphtheria were the lowest for nineteen years; those for enteric fever the lowest ever recorded.

That is one side of the shield. On the other side are the rising claims to sickness benefit under National Health Insurance in all four quarters of the year, the crowded surgeries and out-patient departments, the figures for absenteeism due to sickness, the general complaint of fatigue and of feeling "run down." All this was only to be expected in view of war anxieties, long hours of work, often unaccustomed work in an alien environment, dislocation of home life, shopping and travel and housing difficulties, superadded duties especially at night, lack of holidays, uninteresting food, and that arch-depressant the black-out. But why should these factors stop, apparently, at the production of short-term illness? The greater resort to the doctor may be explained partly by increased health-consciousness. People may have taken to heart the teaching about "positive health" and have come to want "health with a polish on it." They may be more aware of the approaches of illness. The need for medical certificates to excuse absence from work, to obtain dietary specialities, to secure exemption from extra duties, leads people more frequently to the doctor's door. Moreover, if doctors' surgeries are more crowded it must be remembered that there are fewer of them. Again, proprietary "tonics" and drugs are not so easy to obtain, so that there is probably less self-medication or chemist-treatment than there used to be. And the influence of better nourishment upon the mass of the population is a factor that must not be ignored.

But when all these things are allowed for there remains a large residuum of short-term illness. The strains of war are cumulative, and the effects on health may be long-term. Even in the present statistics there are danger spots. The increase in new syphilitic infections since the beginning of the war is reckoned at 120%, and new infections of gonorrhoea may be estimated at six or seven times as many as those of syphilis. The mortality from tuberculosis was lower in 1942 than in the previous year, but there was a rise of about 3% in the number of new cases reported. The total number of deaths from cancer rose slightly, though no more than can be explained by the increasing proportion of the population to reach the ages liable to the disease; but the mortality from cancer shows no signs

of yielding to the intensive work in recent years in this field. Epidemic (catarrhal) jaundice, which is occurring widely throughout Europe and the Mediterranean area, shows a disturbing rise in incidence in this country. A special investigation is being undertaken by the Medical Research Council, but there are difficulties to be surmounted, one being the apparent immunity of the usual laboratory animals to the disease, so that immediate results are not to be expected.

The most encouraging note in the Summary Report is not the statistics, which may lead to false inferences, but the reference to the Emergency Medical Service. It may not be realized, so quickly have events happened, that the E.M.S. and the Emergency Public Health Laboratory Service have been the means of bringing a specialist medical service to the whole country. For the first time in our history a specialist medical and nursing staff and the essential equipment, as well as laboratory facilities, are available to the patient in his local hospital or special centre. They are no longer the privilege of only a relatively few patients in the teaching hospitals in the great cities. Standards of care and treatment and diagnosis hitherto known in only a few hospitals have become widely disseminated. This is specially noteworthy in the field of surgery. There are now in England and Wales 21 orthopaedic centres providing facilities for the treatment and rehabilitation of the most complicated cases. They are supplemented by some 300 or 400 fracture departments and clinics of different types. There are eleven special centres for chest injuries, ten for head injuries, four for injuries of the spine, twelve for plastic surgery and jaw injuries, twenty for skin diseases, eleven for neurosis, and many others. Mobile teams for head, chest, and plastic surgery and jaw injuries are based on the majority of the special centres for the treatment of those conditions. Along with all this have gone a vast extension of pathological laboratories and a blood transfusion service which supplies every hospital in the emergency system with a reserve of blood plasma and serum and maintains a large number of blood banks. Another point emphasized in the report—a remarkable document of 50 pages—is the advantage derived from hospital staffs generally from this continual contact with specialists.

RHEUMATIC FEVER

There are few diseases which recall so vividly Martineau's line—*Non est vivere, sed valere vita*—as rheumatic fever and its associated groups of clinical evils, the epidemiology of which is the subject of Prof. John R. Paul's monograph, a second edition of which has recently been published. The actual mortality rate is, of course, very far from negligible, but when one considers the price to be paid in terms of suffering and exclusion from the normal pleasures of active life by those whose hearts have been damaged in youth, an exchange of this enemy against another producing a higher death rate but less long-term invalidity might seem a good bargain for mankind. Prof. Paul and his coadjutors have an interesting story to tell. As so often happens in medical history, one begins with the observations of symptoms and physical signs in different groups of patients, shrewd physicians perceive affinities between apparently different groups, and finally a certain biological unification is effected by discovering a common bacteriological factor—here haemolytic streptococci. At this point the question of innate disposition and environmental or procataretic causes acquires—and their respective shares in the aetiology!

¹ *The Epidemiology of Rheumatic Fever and Some of its Public Health Aspects*. By John R. Paul, M.D. Second edition. Printed for the Actuarial Association by the Metropolitan Life Insurance Company, New York, 1943.

he disease acquire—a new significance, and we have an increase of collective or individual studies of the prevalence and social-economic, climatic, and racial factors which may affect the prevalence or fatality.

This monograph recapitulates the modern history of the subject clearly. More space is naturally given to American work than to that done elsewhere—quite rightly, because more has been done in the field, and the field is more extensive than elsewhere; but European studies are by no means neglected, and in a concluding section on the public health aspect of the disease the London County Council's rheumatism scheme receives well-merited praise. Rheumatism emerges as one of the killing and disabling diseases that fall, relatively as well as absolutely, most severely upon the economically and socially least prosperous classes of a community. Which of the correlates of "poverty"—over-crowding, bad housing, a low standard of nutrition, and, as extreme selectionists might urge, inferior genetic stock—is the most important direct influence might be debated, but most would give first place to that first mentioned so far as concerns incidence, reserving judgment as to the relative importance of the second and third in determining the outcome of the disease. That the elimination or "conquest" of rheumatism is a distant goal most agree. But there is no doubt that early ascertainment of cases and the supervision of youthful patients have done much and will do more to reduce the volume of human suffering and inefficiency. Perusal of this volume may depress some readers, by showing them that the problems to be solved are complex, but will also convince them that much can be done to improve the lot of rheumatic patients.

FRENCH DOCTORS IN REVOLT

Le Médecin Français is the title of an underground newspaper now being published in France by our French colleagues who are taking an active part in the covert war against the occupying enemy. A recent issue tells how the mobilization order for work in Germany affects the medical profession. "Germany," it is stated, "demands 5,000 French doctors, and everything leads us to believe that they will soon be called up. The Bosches are aiming at the physical destruction of our people. To take away our doctors is one of the best ways of achieving this." *Le Médecin Français* describes ways of defeating the mobilization order—for example, by failing to pass as fit the Frenchmen medically examined before deportation, by helping those who try to escape deportation, and by stimulating the population to protest against the enforced departure of medical men for Germany. That this can be no easy matter may be understood when one learns of the advice to doctors issued by Dr. Grasset, "Minister of Health by the grace of Hitler." This unfortunate man has to tell his French colleagues that in the examination of conscripts for Germany "the principle is that there must not be any 'unfit,' or rather that, real invalids apart, the 'unfit' must be the exception; in the present circumstances every individual, even in a bad general state of health, can and must be used, even if only for a job such as clipping railway tickets. . . ." It appears that the Vichy Government had set up "medical councils," supervised by a "Conseil Supérieur," whose members have recently resigned in a body. Commenting on this, *Le Médecin Français* observes: "The Council was the instrument for applying German orders. . . . Its failure is the same as that of any attempt to rebuild France as a country enslaved by a ruthless enemy, and governed by that enemy's lackeys." Another of the Vichy Government's measures opposed by patriotic French doctors is the suppression of what corresponds to our First M.B., and the replacement of it by

the A.M.P. (*Année Médicale Préparatoire*). This, the newspaper points out, is highly injurious to French medicine: "It is a measure that will be dear to the Nazis, and in keeping with their hatred of science and culture." We salute the medical men of France who thus keep alive the spirit of their country through the medium of what must be a unique publication in the history of medical journalism.

MASSIVE VITAMIN D THERAPY IN RICKETS

Although single massive doses of vitamin D were used as early as 1928 for the prevention of rickets in experimental animals, it was not until ten years later that this method was used clinically for the prophylaxis of rickets. During the last five years it has been tried by numerous workers, particularly in Germany by Harnapp,¹ Brockmann,² and Heisler,³ and in America by Vollmer⁴ and Zelson.⁵ They have shown conclusively that infants between the ages of 2 months and 1½ years can be adequately protected against rickets throughout the winter months by administering 400,000 to 600,000 international units of vitamin D in a single dose. This method has recently been re-examined in America by Wolf⁶ and by Rambar and his associates,⁷ who report that it is effective, safe, time-saving, cheap, and free from toxic effects. The vitamin D may be given either in daily doses of 1,000 i.u. up to two or three months, followed by a single dose of 600,000 i.u., which is repeated four to six months later; or the infant is given 50,000 i.u. at one and two months respectively, and then a single dose of 600,000 i.u. at three months, this dose being repeated from four to six months later. According to the American authors these large doses were well tolerated and no toxic manifestations were observed, such as loss in weight, vomiting, or metastatic calcification. This is interesting in view of some of the older reports on the toxicity of large doses of vitamin D. Many of these are open to criticism because impure preparations, such as the old vigantol, were used. These were not properly standardized and contained toxisterols and lumisterol derived from the irradiation of ergosterol, as well as vitamin D₂. Moreover, they were given in very large doses over periods of several months. Wolf and Rambar used a vitamin D preparation free from impurities obtained by irradiating vaporized ergosterol in a partial vacuum. The cases of metastatic calcification reported in the vitamin D literature must be evaluated in the light of our present knowledge of the part played by kidney disease in calcium metabolism. Laboratory studies by Rambar on the infants receiving massive doses of vitamin D revealed no significant changes in red and white cell counts, haemoglobin, and blood calcium and phosphorus.

The administration of a single dose of vitamin D to an infant only two or three times a year for the prophylaxis of rickets has considerable possibilities as a public health measure. It may well become the method of choice in the future. It saves the time of the mother and the doctor; it is cheap; and it is very suitable in clinic practice when dealing with uncooperative, unintelligent, or careless parents. If the vitamin D were given at the clinic in one dose there would be no doubt about the infant's receiving it. The method would also appear to have possibilities in the occupied countries of Europe, where the disease is rife owing to lack of animal fats. When we are able to give medical aid to the unfortunate children there, massive vitamin D therapy will have much to recommend it.

PAPER CONTROL AND THE WAR OF IDEAS

Mr. Stanley Unwin has drawn attention in the *Times* to the paradox whereby the very books which ought to be readily available are increasingly difficult to obtain. Conversely, the supply of indifferent books by newcomers to publishing steadily increases. No one may start a new periodical or open a new shop without a permit, but anyone can start a new book-publishing business. And a newcomer to publishing is free to use any paper he can persuade any printer to provide, whereas an established publisher (and this includes the medical and scientific publisher) is compelled to declare his use of any such paper and to have its equivalent deducted from his meagre allowance. Hence old-established firms of repute have to announce that more and more of their essential books are "out of stock" for lack of enough paper to reprint them. The short-sighted paper policy which Mr. Unwin condemns made little discrimination between medical and scientific journals actively promoting the war effort, and worthless or mischievous periodicals. On a wide and statesmanlike view it was false economy in March, 1942, that compelled medical journals of the highest standing, already shrunk almost beyond recognition, to choose between cutting down circulation or still further cutting down pages. In our case there was no alternative because membership of the B.M.A. gives a right to a weekly copy of the *B.M.J.*, and the number of members has risen by 6,000 since the outbreak of war to a total to-day of well over 44,000. Our present ration of paper is wholly inadequate for the needs of the profession, and much valuable information is therefore delayed at a time when quick diffusion of new ideas and new methods may be of the first importance. The medical curriculum has been compressed so that students may qualify earlier and take their part in war work for the Forces and civil population. These new entrants, no less than their seniors, require postgraduate education through the professional journals. They cannot be properly served with the amount of printing paper now allowed to the medical press. There is colossal waste of paper for trivial purposes, and responsible editors and publishers of medical works should not have to plead and plead their case before the Ministry of Supply. In September, 1939, the *B.M.J.* voluntarily reduced its size as a matter of foresight and public duty. When paper control was enforced we began to suffer progressively severe cuts. We have done all that is possible to economize space and to restrict sales; so, no doubt, have contemporaries who print far fewer copies. Our main grievance—and in this we stand perforce alone—is against the unyielding attitude of the Paper Controller towards a valid plea for a percentage increase in ration to meet the demands of an ever-growing clientele, early all of whom are engaged in vital war work and must have their knowledge replenished and kept up to date. It is well known that the lay newspapers have lately been allowed a rather better ration of paper. Whatever the reason for this, the medical press should have no worse treatment: our argument is irrefutable.

DILANTIN FOR NON-EPILEPTIC PSYCHOSES

Despite the great advances in the treatment of psychoses by insulin, convulsions, and leucotomy, the need for a fully satisfactory sedative in states of chronic psychotic excitement is still pressing. Severe excitement and violence, particularly in katatonic schizophrenia, remain probably the most difficult problem of mental nursing; so much so that the rather heroic measure of leucotomy is being used more and more to relieve these symptoms in cases in which

recovery is not to be expected. Kalinowsky and Putnam have lately shown that diphenyl hydantoinate (dilantin epanutin) can diminish excitement and irritability in psychotic states, almost irrespective of the type of psychosis. They claim no more than a symptomatic improvement, which tends to wane on withdrawal of the drug. Nevertheless, when the fact is faced that none of the usual sedatives is altogether satisfactory owing to cumulative toxic or hypnotic properties, this encouraging report of dilantin is welcome. Dilantin, it is true, has toxic effects, but with care can be used harmlessly for long periods in epilepsy; its hypnotic action is conspicuously weak.

Of wider interest is the possible bearing of this work on our knowledge of the origin of psychotic irritability and excitement. Epilepsy is recognized as a "paroxysmal cerebral dysrhythmia,"¹ and abnormal electro-encephalographic (E.E.G.) records are common in epileptics. Abnormal E.E.G.s are seen occasionally in katatonic schizophrenia,² and, although the resemblance appears to be merely superficial, it has been pointed out³ that the abnormal pattern found in schizophrenia resembles that predominantly associated with epileptics subject to "psychomotor equivalent" attacks. In 1938 Merritt and Putnam⁴ observed that sodium diphenyl hydantoinate was particularly beneficial in psychomotor equivalents, so that its effect on schizophrenic excitement is logical and adds support to the view that cerebral dysrhythmia may underlie some schizophrenic reactions.

GIFT TO THE ROYAL COLLEGE OF SURGEONS

As was announced in the *Times* last week, Mr. W. H. Collins of Wexham Park, Buckinghamshire, has made a gift of £100,000 to the Royal College of Surgeons of England for the endowment of the Department of Pathology and the institution of a Chair of Human and Comparative Pathology. And Mr. Collins has added to his munificence by making provision in his will for a bequest of a further £100,000 for the endowment of the Department of Anatomy and the institution of a Chair of Human and Comparative Anatomy. Among Mr. Collins's benefactions to medicine was the building and equipping of the X-ray Diagnosis Department at the Middlesex Hospital. In a letter which Sir Alfred Webb-Johnson read before the Council of the College, Mr. Collins said that he had been much impressed by the value of the Departments of Anatomy and Pathology, which had made the College famous the world over. He had seen what grievous injury the departments had suffered as a result of enemy action, and appreciated what a big task it would be to restore them: "To embark upon this task it is essential that the Departments should have an assured income from endowments. . . . I trust that my gifts will enable the Council to proceed with confidence with their responsible task and to engage the services of men of outstanding ability to assist them in their labours." It will be remembered that the buildings of the Royal College of Surgeons in Lincoln's Inn Fields were badly damaged in air raids in 1941, when most of the Hunterian Collection of the Museum of the College was lost.

We much regret to announce the death in Melbourne of Dr. R. H. Fetherston, Director-General of Medical Services of Australia in the war of 1914-18, and a Vice-President of the B.M.A.

THE EFFECT OF SUPPLEMENTS OF VITAMINS AND MINERALS ON THE HEALTH OF GIRLS*

BY

HILDA FOWKE, D.Sc.

In the autumn of 1940 the opportunity arose to study the effect on the health of girls between the ages of 8 and 12 years of adding a bar of fortified chocolate to the diets provided in five North Country orphanages. At the time the experiment was started few tests had been carried out in which chocolate had been used as a vehicle for vitamin and mineral supplements. Quite apart, therefore, from the direct dietary implications of the study, there was the interest of investigating the practicability of this use of fortified chocolate. The success of the test with chocolate encouraged its more recent use in a wider field. This experiment was undertaken under the direction of the Ministry of Food and the Ministry of Health. The specification of the "fortified" chocolate was devised by the Scientific Advisers Division of the Ministry of Food.

The Experiment

In all, 214 girls took part in the experiment. In each of the five institutions the children were divided at random into two approximately equal groups. One group, amounting to 110, received the fortified chocolate, and the remaining 104 girls were given a similar chocolate to which no nutrients had been added. The daily supplement of 1 oz. of fortified chocolate contained 2,000 i.u. of vitamin A, 250 i.u. of vitamin B₁, 100 i.u. of vitamin D, 35 mg. of vitamin C, 250 mg. of calcium, and 10 mg. of iron. The experiment continued from Feb., 1941, to April, 1942.

The composition of the diet provided by the orphanages was determined on two occasions—in Feb., 1941, immediately before the experiment began, and in Sept., 1941, seven months later. The assessment was made by weighing all the uncooked food provided for the children during three consecutive days. Nutrients were calculated from unpublished tables compiled by the Medical Research Council. No allowance was made for cooking losses or for table waste. The latter was probably small, as the orphans were accustomed to clear up everything put on their plates. The nutritional value of the diets is given in the table below.

Daily Nutrients provided for Girls of 8 to 12 Years in the Uncooked Food at Five Orphanages

	Home	Calories	Animal Protein	Calcium	Iron	Vit. A	Vit. B ₁	Vit. C
			g.	g.	mg.	i.u.	i.u.	mg.
Feb., 1941.	M	2,590	29	0.74	14	3,510	480	52
	L	2,480	21	0.57	12	2,410	410	48
	N	2,250	25	0.83	12	3,030	310	22
	H	1,850	16	0.59	9	1,780	380	31
	K	1,830	19	0.52	10	1,520	330	39
Sept., 1941.	M	2,870	34	1.18	14	3,420	590	87
	L	2,340	28	0.89	14	3,780	450	76
	N	2,490	31	0.90	20	6,540	700	85
	H	2,120	22	0.80	12	1,900	470	53
	K	2,330	20	0.61	11	1,460	410	63
Probable requirements		2,300	30	1.00	12	4,000	400	70

It will be seen that conditions in the different institutions varied. On the first survey the diets at H and K were deficient in all the nutrients studied, as well as in calories. The children in home M, as might be expected from the figures, seemed in general appearance best fed and happiest. The improvement in all the diets between February and September was due partly to a general amelioration in the national food supply, exemplified by an increase in rations of cheese from 1 oz. to 3 oz. a week, in jam from 8 oz. to 1 lb. a month, and an improved supply of milk, and partly to a greater self-consciousness, especially on the part of the worse-managed institutions, arising from the experiment itself.

* Permission has been given by the Ministry of Food for this work to be published. It is hoped to publish the report in full in another journal.

In order to measure whether the nutritional supplements contained in the chocolate had any effect on the health of the children the following tests were made. At the beginning of the experiment, after six months, and at the end after a year, heights and weights were recorded and a complete medical examination carried out. Additional measurements and tests were: sitting height, chest circumference, the time the breath could be held, the lifting power measured by a spring dynamometer, and the length of time each child could hang from a horizontal bar.

It can briefly be said that by the use of these tests we could detect no statistically significant differences due to the consumption of additional vitamins A, B₁, and C, calcium, and iron in chocolate over the period of a year. It appears, therefore, either that the basic diet of the children, which at the beginning of the experiment seemed to be defective, became of itself sufficiently ample in the nutrients studied, or that the clinical tests were not sensitive enough to detect minor signs of malnutrition.

Comment

The experience gained during the course of this work suggests that chocolate is a particularly good medium for the incorporation of vitamin and mineral factors. Among its qualities are: that it is of itself a food and not a medicine, that its taste is popular and strong enough to conceal that of substances added to it, and, most important of all, that the cocoa butter in it is an excellent anti-oxidant which prevents the destruction of sensitive vitamins during storage. In the course of this experiment samples of the fortified chocolate were kept at room temperature for several months, and the stability of vitamins A, B₁, and C measured in the laboratories of the Medical Research Council at Cambridge. The results are given below.

Effect of Storage at Room Temperature on Vitamins A, B₁, and C incorporated in Chocolate also containing Added Calcium and Iron

	Vitamin A (i.u. per oz.)	Vitamin B ₁ (i.u. per oz.)	Vitamin C (mg. per oz.)
Dec. 1941	1,490	280	22
Feb., 1942	1,650	252	26
April, 1942	1,600	249	22

This investigation was only made possible by the generosity of Mrs. Merlin Minshall, who sponsored the work as a memorial to her father, the late Dr. Llewellyn.

MEDICAL RELIEF IN THEATRES OF WAR

We have received from the Office of Foreign Relief and Rehabilitation Operations at Washington a report on activities of medical personnel attached to its North African Mission and on its plans for health and medical measures in future relief theatres.

Public health experts on the staff of O.F.R.R.O. are making detailed arrangements to follow up and supplement measures of the Army Medical Corps to forestall the possibility of major epidemics developing in the wake of war. Health and medical care preparations were undertaken on the basis of statistics which showed that malnourishment and a breakdown in sanitary services and standards which invariably accompany warfare resulted in the first world war in deaths and impaired health among civilians considerably in excess of deaths and mutilations due to battle. The world-wide scope of the present war, with great dislocations of populations, holds even greater possibilities of danger. Recognizing that measures of control must be initiated and followed up during every stage of military operations, O.F.R.R.O. is going ahead with sanitary programmes to accompany Allied arms in all relief theatres.

Experience in North Africa

Experience in medical relief is being acquired in North Africa, where U.S. public health officers have been at work for the past six months as members of a relief and rehabilitation mission. These officers have been attached by General Eisenhower to the military command and given supervisory responsibility for civilian health in the North African region, working in close co-operation with medical officers of the Allied Armies. In any measures affecting the civilian population they work through the French civil authorities, and make use of existing health and governmental services and French professional personnel in the execution of plans. Development of the North African campaign made health and medical

problems less complicated than had been anticipated. It had been feared that the severe bombardment of Axis forces in Tunis might create a serious health problem through damage to the water supply and sewage disposal systems of the city. Yet so precisely had Allied bombers concentrated on the harbour area that only minor damage of this type occurred in the city, and fears that typhoid and dysentery might become serious in Tunis and spread to other areas were promptly dissipated by rapid repairs effected by military engineers. Typhus, too, had been feared because it was known that only a year before there had been some 25,000 active cases in the region. Yet this year only a few scattered cases were reported in Tunisia. It was assumed there would be damage to hospital facilities, but in Tunis the hospitals were found intact with 1,000 empty beds. Although some of the other Tunisian cities, such as Bizerta and Susa, had had rougher treatment, the public health officers reported in general after the campaign that health conditions throughout the area were normal in virtually every respect. Captured atabrin was on hand for the malaria cases and "sulpha" drugs were obtained from military stores to make good the two most serious deficiencies in medical supplies. In Tunisia public health officers sent by O.F.R.R.O. worked closely with relief officials who were distributing food. Elsewhere in North Africa medical personnel have had a variety of duties. A principal task since the mission arrived early in the year has been technical assistance to French authorities in estimating and adjusting to available supply requests to Lend-Lease for drugs, medicines, and other medical supplies. Another task was to give aid to the French authorities in efforts to restore normal health services in rural areas and cities of the region. Notably, Oran was helped in this manner by the establishment of a modern health department for the city. At other points, delousing stations were established near cities to prevent the carrying of typhus-bearing lice into the coastal areas during the periodic migration of the Arab population to city markets. Operating through civilian authorities, continuous support has been given to military work for the control of venereal disease.

Preparations for Relief Elsewhere

While much of the health programme for North Africa necessarily had to be improvised on the spot, preparations were being made in Washington for more systematic arrangements in future relief theatres. Several different types of "packaged" units of medical supplies are being assembled for immediate shipment to any area of need. One is a basic emergency unit equipped with the minimal medical supplies for control of the more common diseases of world-wide occurrence. This unit is designed to care for the needs of a population group of 100,000 people for a period of one month. Multiples of this unit can be immediately shipped into any area of medical relief activities during initial stages of operations. Secondly, plans are being drawn up for a larger standard unit of supplies made up of the various drugs and surgical and sanitary equipment required by a population group of 1,000,000 people over a three-months period. This unit could be shipped into an area needing relief when the total health situation of the area had been surveyed and final requirements for medical relief established. Finally, there are special supplemental "packages" made up of supplies for combating diseases peculiar to certain regions or for diseases in epidemic form. Minimum "precautionary reserves" of hospital and laboratory equipment are being packed and kept ready in store for immediate shipment in accordance with needs developing after military action.

The supply of professional and scientific personnel to carry out and supervise health plans in reoccupied countries presents a major problem. While the Nazis have systematically attempted to exterminate professional classes in some countries, it is believed that enough trained personnel will be found in most of the reoccupied regions to carry out the bulk of the work under progressively diminishing supervision. Lists of local health officials, heads of hospitals, selected doctors, nurses, and sanitary engineers, dating from a period immediately before German occupation, are in existence in most of the European countries where action will be taken, and most of these people should be available. A limited number of health officer "teams" are being brought together for service in areas which may be soon opened for relief activities.

Hull and District Provident Society, formed to help members and their families to safeguard themselves against the risk of heavy and unforeseen expenditure arising from nursing home or hospital private ward treatment, and specialist medical or surgical service, was inaugurated on Oct. 6. Sir E. Farquhar Buzzard (chairman of the Medical Advisory Council of the Nuffield Provincial Hospitals Trust) said that his conviction as to the need for mutual insurance under a provident scheme had not been affected in the slightest by any statements made by the Minister of Health as to the comprehensive health service which he envisaged. Sir Farquhar was certain that no comprehensive health service could provide for the middle class anything like the kind of amenities and comforts that would be available under the provident society's scheme, with choice of physicians and surgeons.

MEDICAL DEFENCE UNION

In his address from the chair at the annual meeting of the Medical Defence Union, the president, Dr. JAMES FENTON, said that the war had not reduced the number of cases to which the Union was called upon to give attention. Litigation, in fact, continued on an increasing scale. "The missing swab, the burn by radiological or diathermy apparatus, the ether explosion, the missed fracture, the dispute account with allegations of negligence, seem to come before us with greater frequency than in the past."

G.M.C. and M.D.U.

The only case to which he referred in detail was that in which the Union gave full assistance to its member Dr. Spackman in the prosecution of his case against the General Medical Council taking it right through from the Divisional Court and the Court of Appeal to the House of Lords, with a very satisfactory result. "For the first time the General Medical Council is confronted with the possibility of making a new investigation by reason of the submission of new facts which would in some instances presumably have an extenuating influence, and in others make a complete rebuttal of a serious offence with which a member may be charged. The decision of the House of Lords is one which will be quoted through the years to come as a distinct benefit accruing not merely to Dr. Spackman but to the profession as a whole." In this connexion he paid a tribute to Mr. Oswald Hempson, the Union solicitor, and Mr. Henry C. Dickens, its counsel. He added that he and other members of the Council of the M.D.U. who were closely acquainted with the work of the General Medical Council held the view, notwithstanding the Spackman episode, that the G.M.C. was well fitted to investigate professional matters. He himself would prefer to be judged by that distinguished body of medical men, familiar with all the dangers and difficulties peculiar to medical practice, than by a civil court. The Union did not in any way object to the Council going to the House of Lords. There was merely a difference of opinion by the legal experts who advised the two bodies, and it was felt that it should be solved once for all. He was anxious to make it clear that the Union had always worked harmoniously with the Council, and, indeed, when the Union prosecuted unregistered practitioners the fines payable to the G.M.C. were generally returned to the Union as a contribution towards the expenses involved.

In conclusion Dr. Fenton issued two warnings. One of these was that doctors returning to practice on demobilization, and who might while on service have terminated their membership of the Union, should consider it their first duty to themselves and their families to satisfy themselves that they were once more registered as members in full benefit. The other was that if the State should assume control of the profession doctors must not take it for granted that membership of the Union would be no longer necessary. If a practitioner was employed by the State his obligation at law remained as before, and the State would not take over the liability for his errors and omissions.

It was reported that during 1942 the number of new members elected to the Union was 1,684, and that the membership now stood at 25,989. The guarantee fund amounted to just over £33,000 and the total funds available were about £141,000. Dr. James Fenton was re-elected president and Mr. E. D. D. Davi treasurer, and Dr. Roche Lynch was appointed chairman of the Council Committee.

WORK AT PAPWORTH

The 26th annual meeting of the Papiworth Village Settlement recently took place, and the report of the committee of management, which is also the governing body of the Village Centre for Curative Treatment and Training that operates the Enham Village Centre, near Andover, is now published.

The pioneer work of the late Sir Pendrill Varrier-Jones is being maintained in all its manifold aspects. Progress has been made in many directions; and the committee of management has taken some important steps to ensure that the loss of Sir Pendrill, at the early age of 57, shall in no way upset the workings of the great organization he built up. Of such steps, the most important is the election of Wing Commander R. R. Trail, M.D., F.R.C.P., to the honorary medical director of Papworth and Enham. Secondly, medical consultative committee has been formed to advise the committee of management upon all matters relating to the medical policy and development of the work of both Enham and Papworth. The chairman is Wing Commander Trail, and the following are members: Sir Walter Langdon-Brown, Mr. G. E. Gask, Dr. F. R. C. Heaf, Mr. J. B. Hunter, Sir Arthur MacNalty, Prof. J. Paterson Ross. In addition, the committee has recognized the invaluable service which the senior officials of the settlements rendered to it.

ndrill Varrier-Jones by forming a board composed of all departments of the organization—medical, nursing, domestic, industrial, appeals, and public relations. This board, with the hon. medical rector as chairman, includes in its membership the chief medical officer, the managing director of the industries, and the matron, and its as a valuable administrative liaison with the committee of management. The committee has thus ensured the unbroken sequence of Sir Pendrill's administration and policy—a mixture of medicine, economics, and sociology; and the results during the last two years fully justify this policy.

The formation of a memorial lecture scheme to commemorate the work of Varrier-Jones is also announced. Two lectures have been delivered, one by Wing Commander Trail on "Early Diagnosis," and the second by Sir Arthur MacNalty on "The Comprehensive attack on Pulmonary Tuberculosis." A third is to be given by r. Geoffrey Marshall, whose subject will be announced later.

Reports of Societies

CLINICAL PHOTOGRAPHY

At a meeting of the Association for Scientific Photography held on Sept. 18 at Middlesex Hospital Dr. H. MANDRILL addressed the particular qualities required in clinical photography. In his opinion these were: (a) a simple straightforward record with perfect definition; (b) a self-explanatory picture, but nevertheless one which did not include unessential portions; (c) a well-presented print, as much care being taken in the mounting and finishing as in a studio portrait; (d) in the case of colour photographs the colour must be true to the original. This was of particular importance in skin diseases which were characterized by the colours of the part affected. It was suggested that a Clinical Group should be formed in the Association, which would discuss the special aspects of this work and compare technique. Another point was the collaboration between the photographers and manufacturers of apparatus. The requirements of clinical photography were in many cases distinct from those of studio or outdoor work, and it would be of great advantage to have certain apparatus specifically designed for the work.

Mr. T. POMFRET KILNER stressed the importance of standardization in technique, particularly in his own sphere of plastic surgery. The photographs taken before and after treatment required to be strictly comparable as regards type of film, exposure, lighting, etc. He illustrated his remarks with views of a simple equipment employing a Leica camera and photo-flood lighting which enabled photographs to be taken at any angle and which could also be used for copying radiographs or documents. He recommended that ortho materials be used for the majority of work.

Miss HILDA MARSDEN showed examples of the work done in clinical photography at the Christie Hospital, Manchester, using a half-plate camera with studio technique. She laid special stress on the importance of lighting, particularly in delineating the outlines of growths, etc.

In the discussion which followed the papers Mr. ANDREWS (L.C.C.) showed illustrations of a convenient set-up for photographing patients in bed which was made with the aid of a pair of steps such as is always available in a hospital. The camera was fitted to the top of the steps with the usual ball-and-socket joint and could be directed in any required position. By means of interchangeable lenses and lights, also fitted to the top of the steps at varying angles, he was able to take a variety of photographs of a patient from head only to full-length. He had found that a 4½-in. lens was adequate for full-length and an 8-in. for head-and-shoulders. A 14-in. lens gave a close-up of an individual part of the patient lying flat about 5 ft. below the camera. As a matter of interest Mr. Andrews showed a photograph of a patient with one brown eye and one blue, taken with orthochromatic film without a filter. Only one photo-flood lamp was used and the colour rendering was excellent.

Mr. HENNELL (Metal Box Co.) said that he had taken several thousand clinical photographs in colour during the war, and used sashalite bulbs exclusively for illumination. He considered this was the best method for tackling a variety of jobs, and agreed with Mr. Kilner on the need for standardization. He exhibited several samples of colour prints on paper.

Several other speakers took part in the discussion, and it was generally agreed that clinical photography should be undertaken by a professional photographer, who would find it advantageous to make a special study of physiology and anatomy. It was not thought reasonable to expect a doctor or surgeon to do his own routine photography, and it was also pointed out that the majority of hospitals, while equipped for x-ray work, were not well equipped for clinical photography.

Those interested in the formation of the Clinical Photography Section should write to the secretary of the Association, Mr. R. M. Weston, at Houndwood, Farley, nr. Salisbury, Wilts.

CLINICAL PATHOLOGY

The summer meeting of the Association of Clinical Pathologists held at the Department of Pathology, Cambridge, was notable for a number of reviews of subjects of current importance. There is space here for only a brief summary of some of these and for mention of one or two of the demonstrations.

Typhus.—C. H. ANDREWS grouped the varieties of typhus thus: (a) Type OX19—classical typhus, endemic typhus, Mexican typhus, Brill's disease, and shop typhus (Malaya), with the louse and rat flea as vectors, and all giving good agglutination with OX19 but very little or none with OX2 or OXK. (b) Type XK—tsutsugamushi, scrub typhus (Malaya), mite fever (E. Indies), with the mite as vector, and agglutinating well with OXK but not with the other two antigens. (c) Type undetermined—Rocky Mountain spotted fever, São Paulo typhus, fièvre boutonneuse, tick-borne typhus of S. Africa, India, Kenya, all carried by ticks and giving poor agglutination with all three classical antigens.

Rh Factor.—P. L. MOLLISON said that 88 mothers whose infants were affected with haemolytic disease had been tested so far. Of these 85 were Rh-negative and only 3 Rh-positive. Anti-Rh agglutinins were found in the sera of 82 of the 85 Rh-negative women. In these cases the peak of the immune response to the Rh agglutinin was usually reached between the fifth and twentieth days after delivery, and this was therefore the most favourable time for examination. In two of the cases in which the mother was Rh-positive the destruction of the foetal erythrocytes was apparently due to very potent immune anti-B agglutinins. GERTRUDE PLAUT dealt with the clinical importance of the Rh factor, and G. L. TAYLOR demonstrated the technique. In the discussion E. N. ALLOTT asked whether there was any genetic linkage in the inheritance of the ABO and Rh groups. Dr. MOLLISON replied there was none.

Pathogenic Anaerobes.—F. A. KNOTT showed a series of tables summarizing methods and media for the detection of pathogenic anaerobes. The use of Fe media, neutralization of sulphonamide and suppression of contaminants, media giving good growth without anaerobe jars, and methods of identifying the specific toxins—all help to detect the presence of pathogenic strains without first going through the time-consuming process of isolating pure cultures. Secondly, the early detection of haemolysin and ferments such as lecithinase and hyaluronidase may give valuable early indication whether infection is likely to spread. The results in animal work give high promise of value in the management of wounds in man. Dr. KNOTT stressed that the M.R.C. War Memorandum No. 2, revised edition, is of high value to workers in this field.

Biopsy of Endometrium.—O. C. LLOYD observed that biopsy of the endometrium was of great value in the diagnosis of abortion and of malignant disease as well as in sterility and menorrhagia. In these latter conditions it was advisable to have a biopsy between the eighteenth and twentieth days of the cycle, when early secretory differentiation might reveal relative deficiency of the action of the luteinizing hormone on the endometrium.

Cutaneous Diphtheria in an Infant.—E. N. DAVEY showed specimens from a baby 7 weeks old which had developed during life a slough from thigh to navel and also behind the ear. The mother, who was Schick-negative, yielded the same type of *C. diphtheriae* as that obtained from the child's lesions, the mother being infected in nose, throat, and vagina. Apparently the child was protected by the maternal antitoxin in the milk so long as it was breast-fed. It died nine days after the cessation of breast-feeding.

BURNS OF EYELIDS AND CONJUNCTIVA

At a meeting of the Section of Ophthalmology of the Royal Society of Medicine on Oct. 8, with Mr. F. A. JULER presiding, a discussion was held on burns of the eyelids and conjunctiva.

Naval Experience

Surg. Rear-Adml. C. P. G. WAKELEY said that in the last war, in the Navy, the first-aid dressing used for burns was picric acid, but the large number of cases of burns which occurred in the Battle of Jutland showed this to be of no use whatever, because when left on it coagulated the skin to such an extent as to convert a second-degree into a third-degree burn. The conclusion was reached even as far back as 1916 that there were two fundamental things to be realized in the case of burns: the need for elimination of sepsis, and the need for skin grafting in the third-degree or deep burn. He then went on to speak of the methods of protection used in this war for gunners and other men whose eyes and face in particular were exposed to this danger. It consisted of the ordinary cellulose acetate goggles with certain heat-resisting material for the face, the whole of the gear being of such a character that it could be stowed away in the steel helmet when not in use. Since the introduction of this protective device the incidence of burns of the face had been very small indeed.

The speaker showed colour photographs of a number of cases treated with triple-dye jelly which had done well, the oedema clearing up and no permanent scar resulting. The difficulty in the Navy was that many of the burns occurred in small vessels on which there was no medical officer and which sometimes could not get the patient to hospital for five or six days. It was very necessary in these small ships to instruct those concerned in the use of a coagulant which prevented excessive fluid loss and was also antiseptic. At the beginning of the war it was thought that every case of burn received at hospital should have intravenous plasma or saline. To-day only one in ten was given intravenous therapy; the medical officers and nursing staff were instructed that, in general, patients suffering from burns should be given fluid by mouth. Common sense and clinical acumen were far more important in saving life than was scientific investigation. Certainly if there were only a few cases the fullest investigations should be carried out, but with a crowd of patients this was impossible. Moreover, if patients were given intravenous therapy they began to take a suspicious view of their own state, whereas if they were asked only to drink a sweetened fluid the picture was very different. He thought there had been some tendency to swing away from a rational form of treatment into a super-scientific treatment, which was to be deprecated in war emergencies.

Types of Burns in the R.A.F.

Fl. Lieut. D. C. BODENHAM said that from the point of view of treatment two types of burns were important: the superficial second-degree burn affecting only the layer of epithelium, and the destructive or third-degree burn in which practically all the dermis was destroyed. But it was surprising how often epithelial island cells survived, from which, by spreading and coalescence, healing occurred. With a large amount of destruction, however, this was much too slow, and it became a question of skin grafting. One marked feature of burns of the face, owing to the loose supporting tissues, was the great amount of oedema which developed even with a moderate burn. The oedema remained at its maximum usually for from 12 to 36 hours and then began to subside. It was remarkable how rarely, even in the most destructive cases, the globe was involved, but it was always the duty of the surgeon to examine it when the case was first seen. In burns due to exposure to the instantaneous combustion of magnesium used in flash bombs conjunctival involvement was very common, though the exposure was so brief that usually only the most superficial layers of the skin were burned. The globe was somewhat protected in these cases by the constant film of moisture which bathed the cornea and the conjunctiva. Sometimes tattooing of the globe occurred due to minute particles driven in by the force of the explosion, and too small and numerous to be

removed surgically. Treatment of burns in the R.A.F. was on simple principles—to prevent infection and to do as little harm as possible to the healing tissues. If a case did not heal on its own it should be assisted by skin grafting. An application of sulphonamide, either as powder or the 3% cream advocated by Dr. Colebrook, was in use, applied on a coarse mesh petroleum jelly gauze, making a very soft and gentle non-traumatic dressing. Penicillin, applied for 24 hours, has been found effective in eliminating streptococci and staphylococci from granulating surfaces. Keratitis was not infrequent in these eye burns. In the slighter cases simple measures might be employed, such as constantly keeping the globe moist with saline and using a lubricant, but in the more severe cases a contact glass had to be used as a mechanical protection.

Squad. Ldr. G. T. W. CASHELL said that in the burns seen in the R.A.F. it was remarkable that while there was seen a pronounced effect on the eyelids and face there was often practically no effect on the globe, apart from a little oedema of the conjunctiva, and particularly of the cornea, due to spread from surrounding tissues. In the case of flash explosions, however, the whole of the cornea and the conjunctiva might be severely pitted with particles of the bomb. Some of these cases did extremely well even though nothing was done to them; in others there might be severe ulceration or extreme tattooing of the sclera. He showed one case in which there had been complete obliteration of the lower conjunctival fornix due to an incendiary bomb. A skin graft was put into the lower fornix, but the eye remained extremely irritable and eventually the skin graft was excised and replaced by mucous graft, with mucous membrane obtained from inside the lower lid, with a satisfactory result.

Wing Cmdr. J. E. NEELEY gave an analysis of the cases of burns received at one R.A.F. hospital. Out of 120 cases the face was affected in 80%, and of this 80% ectropion was present in 20% and 5% had an affection of the globe.

Mr. T. POMFRET KILNER showed a film illustrating the grafting treatment of ectropion. The case was not one of burn but of lupus; nevertheless the procedure was instructive. He said that in the case of severe eyelid burn there was a question but that grafting should take place at as early a stage as possible. It was important to graft only one eyelid at a time. Very thin skin might be applied; it seemed to thicken up nicely and take up a reasonable colour match with the rest. One ought not to be over-much depressed if the eyelids contracted again after the first graft. The graft would still have served a useful purpose, and a more cosmetic result could be obtained quite easily at a later date. He used "mastisol" to avoid any sliding of the dressing over the raw surface. After-care was important. The patient should be carefully instructed how to carry out massage, preferably with aniline cream.

Mr. FREDERICK RIDLEY mentioned the value of the full salar bath in getting rid of blepharospasm and photophobia in these cases. It was wise to put the patient on 10% iodol night an ointment and 1% atropine at midday. This did no harm and ensured the best position if later on trouble should develop. Mr. Ridley demonstrated a device for obtaining a moulded acrylic mask and its fixation when there was a good bearing surface (an unburned surface) on the forehead and nose, and again when no skin-bearing surface was available. This was really the fitting of an artificial eyelid which could be worn day and night and was very comfortable. But he emphasized the rarity with which such procedures became necessary. He had been surprised to hear a previous speaker comment on the frequency of keratitis. In his experience the development of this condition was infrequent.

H. H. Perlman, A. M. Dannenberg, and N. Sokoloff (*J. Amer. med. Ass.*, 1942, 120, 1003) made a study of the excretion of nicotine in the milk and urine of 55 primiparae and multiparae from 18 to 48 hours after delivery, addicted to cigarette smoking with the following results: (1) Nicotine was excreted in the milk and urine of all the smokers. (2) Much larger quantities of nicotine were excreted in the urine than in the milk. (3) There was a definite correlation between the quantity of nicotine excreted in the milk and urine and the number of cigarettes smoked. (4) Lactation was little, if at all, affected by the smoking of cigarettes. (5) The nurslings were apparently unaffected by the quantity of nicotine ingested with the milk.

Correspondence

Wartime Diet for Peptic Ulcer Patients

SIR.—Dr. J. B. W. Rowe in his letter to the *Journal* of Oct. 9 rightly stresses the importance of providing people liable to peptic ulcer with sufficient easily digestible food for meals at regular and short intervals. The Ministry of Food has already done this. If the daily allowance of a quart of milk is wisely used there should be little difficulty in keeping free from recurrences when the ulcer has soundly healed, so long as other and more important factors than diet are kept in mind. The quart of milk and the whole of the sweet ration in the form of plain chocolate should be used for intermediate feeds, so that the patient does not fast for more than two hours, or in exceptional cases more than one and a half or even one hour at a time. The importance of frequent feeds in prophylaxis was emphasized twenty-five years ago by Sippy, whose patients always took a bottle of milk with them to their work so that they could drink a few ounces every hour.

The constitution of the main meals is of comparatively small importance. With the exception of such gross "roughage" as pips, tough skins, and vegetable fibres, there is no food intrinsically bad for ulcer, and I see no advantage in substituting cheese for meat, as suggested by Dr. Rowe. The food should be well cooked and thoroughly chewed, and the evening meal should not be eaten until the patient has rested, if he returns home exhausted after a long day's work. These conditions may be difficult to attain, but they are not a matter for the Ministry of Health.

Anxiety is the chief cause of recurrence, and everything possible should be done to help the patient to face his worries with equanimity. Phenobarbitone for insomnia and in small doses during the day to diminish nervous irritability is often more useful than alkalis. During periods of special stress complete rest and strict ulcer diet on Sundays, even in the absence of symptoms, may prevent a recurrence. Lastly, smoking should be prohibited or strictly rationed.—I am, etc.,
Oxford.

ARTHUR HURST.

Peptic Ulcer in Youth

SIR.—In your issue of Sept. 25 (p. 403) Prof. Grey Turner mentions Sir Joseph Leech's case of a perforated gastric ulcer in a boy of 13. I remembered this when I saw recently a young man, just 19, upon whom I performed a posterior gastro-enterostomy earlier in the year for advanced pyloric stenosis. He had suffered from periods of indigestion for many years and certainly when at school. The pain had become persistent when I saw him last May, and he was vomiting after meals. He had an enormously distended stomach. The radiograph (Dr. Wilkie) showed the stomach full of the barium 24 hours after the meal, and clinically I suspected he might have a condition of the pylorus akin to congenital stenosis found in babies, but at operation there was the typical fibrosis of chronic ulceration of the first part of the duodenum with adhesion to the liver.

I wondered how long this youth must have had his duodenal ulcer, and if pyloric stenosis had called for surgery at an age earlier than 18. It would not surprise me if Prof. Grey Turner has knowledge of a younger case than this one.—I am, etc.,
Sheffield.

H. BLACOW YATES.

Recovery of Bladder Function after Long Disuse

SIR.—In the remarkable case recorded by Prof. Rendle Short (*Journal*, Oct. 9, p. 464) recovery of bladder function took place after 21 years of suprapubic drainage. This success, in the extraordinary circumstances described, is high tribute to surgical skill and enterprise. No less is it a tribute to the remarkable adaptability of the urinary bladder. This power of recovery after long disuse is well seen in cases of vesico-vaginal fistula. Among my records are several examples of long-standing urinary incontinence; yet, with one partial exception (see below), complete function has been restored in every case. The following are cases in point.

1. Fistula of 9 years' standing. Urethro-vesical junction involved with considerable destruction of tissue. Seven previous operations—two by the suprapubic route, five by the vaginal route. Patient then told that she was incurable. Fistula closed by Sims's type operation. Complete recovery in every respect.

2. Fistula of 28 years' standing. Two previous operations; patient told she was incurable. Closure of fistula by Sims's technique. Complete recovery in every respect. (It was calculated that during the period of disability this patient had used about 6,000 bales of cotton-wool, and had washed considerably more than 50,000 towels!)

By contrast, the following is a case in which treatment has been only partly successful.

3. Fistula of 2 years' standing. History of obstructed labour, followed by gas-gangrene infection. Large sloughs came away in the puerperium; this resulted, as was subsequently discovered, in loss of the whole of the uterus and anterior vaginal wall, including part of the urethra. Patient had had eight or nine previous operations, some by the abdominal, some by the vaginal route. Fistula successfully closed by Sim's type operation. Subsequent operations undertaken to lengthen and to narrow the urethra. Patient now has fair bladder control, but capacity is only about 8 oz.; deficient sphincter action prevents accommodation of more fluid. This is a recent case, and progress is still being watched.

With the experience of these and other cases I venture to say that no vesico-vaginal fistula need be regarded as hopeless because of the long duration of urinary incontinence. Successful closure with full recovery of bladder function is almost always possible provided that the sphincteric region has not been entirely destroyed. Further, I believe that, with rare exceptions, vesico-vaginal fistulae are best closed by a vaginal operation based on the technique of Marion Sims.—I am, etc.,
Oxford.

CHASSAR MOIR.

Mosquitoes and Static Water Tanks

SIR.—In a letter appearing under the above heading on Oct. 2 your correspondent Dr. A. G. Newell directs attention to the use (in India) of larvivorous fish for preventing mosquito breeding, and advocates the application of this method of control to the case of static water tanks in this country. I venture to point out that even in India the method in question is subject to many limitations. According to Col. G. Covell, Director of the Malaria Survey of India, these are as under:

1. Fish are effective only if present in sufficient numbers.
2. They are completely effective only in the absence of all weed and floating debris.
3. Small boys can be relied upon to catch them if they get the opportunity.
4. Over-zealous persons are apt to introduce other and larger species which may prey on them.
5. If there is not sufficient food for them they will eat their own young, so that breeding places must be periodically re-stocked.
6. Constant inspection is needed to see that the fish are flourishing and are in sufficient numbers, and that the water is free from horizontal vegetation and floatage.
7. In order to carry out these inspections, and to keep up a sufficient stock of fish for the various breeding places, a special staff is necessary.

In view of the above disadvantages Col. Covell considers 'that "the use of fish as a measure of malaria control, though useful in certain conditions (e.g., in places where for some reason it is impossible to employ any other measure), cannot be said to hold a position of very great importance in India. Their chief value is in the case of wells and ornamental waters.' In this country experience has shown that the large static water tanks now installed in London and many other cities are only too apt to become depositories for waste matter of various kinds, and have then to be emptied for cleaning. This fact constitutes a further disadvantage to be added to Covell's list.

Of other control measures suggested by your correspondent, that of removing tanks from shady situations hardly meets the present case, since *Anopheles maculipennis* (to which his letter chiefly refers) definitely prefers open sunlit places in which to breed. Again, the statement that "leaves or algae will give a certain amount of shade and hiding place for larvae" overlooks the fact that anopheline larvae pass their existence clinging to the upper surface of "just-submerged" filamentous algae, floating leaves, etc., which certainly protect them from their various enemies, but do not provide them with shade.

So far as I am aware, the only large built-up areas in which the breeding of mosquitoes in static water containers has been

CORRESPONDENCE

systematically studied are London and Portsmouth, in which cities continuous observations were made and recorded throughout the summer and autumn of 1942. In the latter city the only species found breeding were *Anopheles maculipennis* and *Culex pipiens*, the former being recorded 7 times and the latter (which does not bite human beings) 27 times. The records of *A. maculipennis*, however, included four cases in which the larvae were few and far between, while the four others were provided not by excavated sumps in which masses of filamentous algae were growing. In the London area, where an extremely large number of tanks were periodically inspected, the only species found breeding was "man-ignoring" *Culex pipiens*—a state of affairs that I had ventured to predict during the previous year.

It would appear, therefore, that if static water tanks are free of filamentous algae (the growth of which can be inhibited by dissolving a very small proportion of copper sulphate in the water) they are extremely unlikely to become a source of mosquito annoyance. When, however, larvae of *C. pipiens* are found infesting a tank, it may perhaps be thought advisable to kill them by oil or larvicides, lest public apprehension may be aroused by the subsequent appearance of the adult insects. The suggestion that static water tanks should be provided with tight-fitting covers to prevent mosquitoes from laying their eggs on the water is often advanced. In countries abroad, where the yellow-fever carrier *Aedes aegypti* (which breeds in cisterns, garden tanks, and such-like water containers) is prevalent, the covering of tanks of moderate size is a precaution which is not only of vital importance but is also easily carried out. In this country, however, where we are almost exclusively concerned with an entirely harmless mosquito breeding in very large tanks (often of 25 ft., and not infrequently of 50 ft., in diameter), any such procedure would be both unnecessary and (for constructional reasons) impracticable.

Sterility and Contraception

SIR.—In the *Proceedings of the R.S.M.* (Jan., 1943, 36, 105) described some animal experiments, which have since been repeated and remain unchallenged, to show that the premise of R. L. Noble was correct—namely, that the human semen contains a specific growth hormone. At the same time I cited two groups of newly married young women who had been observed over a period of two years. In Group 1 there was no contraception. Of these, 25% conceived in the first few weeks; in 50%, however, pregnancy did not occur until after an average of 7½ months. In Group 2 chemical and mechanical contraceptive methods were rigidly employed for more than one year from the date of marriage, but in 50% the uterus remained virginal—that is, immature—up to the date of writing. (10 months), and conception had not yet occurred. The deduction is that anything or any method which prevents, retards, or alters the normal degree of physiological absorption of human semen from the vagina carries with it during the early months and years of matrimony the risk of future sterility from failure of uterine development, and endocrinal asynchronisation. Surely, therefore, it is very desirable not only to confirm the views of the late Sir Francis Fremantle but to share the very natural anxiety of Dr. Joan Malleson for those women in the Services, war factories, etc., who are so misguidedly employing deleterious methods. Moreover, if further evidence and corroboration be needed let us read the latest written words of I. C. Rubin on the subject (*Bull. N.Y. Acad. Med.*, Aug., 1942, 541): "Contraceptive methods undoubtedly affect fertility for longer or shorter periods after their use has been stopped."

What is the ulterior effect of prolonged use of mechanical plus chemical contraceptives? Some hold that as a result the woman absorbs only fractional doses of seminal hormone from the vaginal mucous membrane, and that these not only

immunize her against her husband's semen but prevent proper growth of the genitalia. Others, among them Kurzrock and Miller, believe that such methods affect the intimate structure of the selective epithelium of the arbor vitae to such an extent that the secretion becomes abnormally viscous, and that it is the presence of leucocytes and debris, the result of congestion, that inhibits not only the lytic penetration of the mucus plug but also the cataphoretic action which normally accounts for chemotaxis. There is little doubt that the state and blockade of the cervix is of great importance. Upshaw (*J. med. Ass. Georgia*, Jan., 1940, 29, 2) and Moore (*Amer. J. Obstet. Gynec.*, Feb., 1940, 39, 269) believe that sterility can be charged to the cervix (apart from the male side of the problem) in 73 and 60% of all patients respectively; whereas Rucker (*Virg. med. J.*, Feb., 1936, 62, 656) states that 36% of primary and 65% of secondary sterility patients become pregnant when treated for existing cervicitis. Non-patency of the Fallopian tubes in cases of primary sterility is fortunate, rare in this country—certainly not more than 14% in a per se study of over 2,500 lipiodolograms during a period of 17 years—a figure that approximates that of Samuel Meaker in Boston, though almost exactly half that recorded by I. C. Rubin using CO₂.

The statistics of three large hospitals and long private experience point to the fact that, apart from the above, almost the commonest cause of sterility is genital hypoplasia (36-40%), where immature ovaries, the result of some depressive constitutional and/or endocrinal cause at the critical period of a girl's early life, produce a reduced number of comparatively infertile ova. Here lies a golden opportunity for preventive medicine and rehabilitation. I entirely agree with Dr. Malleson that research is urgently needed upon the two-patient problem of sterility. Nothing can be more irrational than the setting up of petty sterility clinics which are cut off from the co-operative team work of a properly staffed and properly equipped hospital, for to-day this complicated and comprehensive problem demands the services of an expert gynaecologist, andrologist, biochemist, pathologist, radiologist, radiologist, therapist, and, not the least, a psychiatrist, all working together on the same front in the same hospital for a common end—I am, etc.,

London, W.1.

V. B. GREEN-ARMYTAGH

Methedrine in Surgical Operations

SIR.—In your issue of Sept. 25 (p. 396) the author of the annotation on *d*-desoxyephedrine (methedrine) refers to our work (*Journal*, 1943, 1, 345) with this drug as a pressor agent in surgical operations, and states that "it may be argued that the drug is contraindicated in surgery because its anaesthetic action may lead to the use of more anaesthetic; certainly the dose used by Dodd and Prescott would be greater than that desirable for an unanaesthetized patient."

Methedrine was used by us solely to counteract the serious falls of blood pressure that often occur in major operation under all anaesthetics, including spinal. A study of this value for this purpose. The supposed disadvantage mentioned—that its anaesthetic action may lead to the use of more anaesthetic—is a theoretical one. Many of the operations were under local or spinal anaesthesia and no effect was observed. Patients never became restless. With general anaesthetics the premedication, the anaesthetic, and the post-operative morphine that the patients received were sufficient to annul the anaesthetic effect of methedrine. Anaesthetists who have worked with us have been impressed by the value of the drug, and have not observed that more anaesthetic is required after it has been used.

The dose we used is admittedly greater than that given to the unanaesthetized patient, because it was given only those suffering from a severe fall in blood pressure. Careful recording proved to us that the amounts recommended in our paper met the needs of such patients. We wish to emphasize that we did not administer methedrine as a routine or for the sake of trying its effect, but gave it only to patients undergoing major operation when the systolic blood pressure fell below 80 mm. or the pulse pressure fell below 10 mm. and stay

here for 10 to 20 minutes. A total of 98% of the cases responded satisfactorily.

Your annotator also refers to the possibility of tachyphylaxis—the diminished response to rapidly repeated doses. This is shown by all the sympathomimetic drugs, including methedrine. We found, however, that a single properly assessed dose was effective in restoring the blood pressure in 81% of the cases; of the remaining 19% only 2% failed to respond to repeated injections. Once the blood pressure was restored to its pre-operative level it kept to within 90% of this figure for several hours, for in practically all cases follow-up studies were made in the wards for at least this period.—We are, etc.,

H. DODD.

F. PRESCOTT.

London.

A "Charter of Health"

SIR,—The Recommendations of Council on the future of medical services, which were discussed at the Annual Representative Meeting, constitute an important pronouncement. Recommendation B, with its mention of "security against fear and want," invites comparison with another document, and, representing as it does a sort of "Atlantic Charter of Health," may be widely quoted as the considered opinion of our profession, and influence public opinion for many years to come. The greatest care should therefore have been taken in drafting it to make it as complete and as clear as possible, and by issuing Recommendation B in its present form the Council have missed a great opportunity.

At present the Recommendation, as slightly amended at the A.R.M., reads: "That the health of the people depends primarily upon the social and environmental conditions under which they live and work, upon security against fear and want, upon nutritional standards, upon educational facilities, and upon the facilities for exercise and leisure. The improvement and extension of measures to satisfy these needs should precede or accompany any future organization of medical services."

If the first sentence is intended to be a catalogue of the principal factors which influence health (and that seems to be its legitimate purpose), there are several important omissions.

Taking these in some sort of logical order there are, first, the inborn constitutional factors, which greatly influence the medical history of a patient whatever his environment may be. To be well born is at least as important as to be well educated or well nourished, and from the racial standpoint much more so. It would be a good thing to remind the general public of this fact at the outset. Secondly, if nutrition is specifically mentioned, other essential factors such as protection from the weather and the matters that are ordinarily cared for by the public health services should be mentioned also.

No list of the factors influencing health would be complete without considering the devastating effects of violence, which includes both the violence of war and the lesser violence of industrial accidents and injury on the roads. Equally essential is mention of the powerful effects on health of various forms of infection. Smallpox, influenza, and venereal diseases may strike down people who are perfectly well nourished and educated, with plenty of leisure.

Another serious omission in these days when so large a proportion of ill-health and absence from work is due to psychoneurotic illness is the psychological environment, and I believe most authorities are agreed that in this respect it is the first six years of life that are the most important. This is the period during which the neurotics of adult life are made.

I therefore beg to submit that, in the next edition, Recommendation B should be amended to read somewhat as follows: "Health depends primarily upon: (1) hereditary and inborn nature and constitution; (2) proper and sufficient food, pure water and air, adequate clothing, housing, and fuel; (3) proper disposal of refuse and excreta; (4) freedom from violence, infestation, and infection; (5) a favourable psychological environment, especially in the earliest years; (6) a proper education of mind and body, and a reasonable amount of exercise and leisure; and (7) suitable and congenial surroundings in which to live and work; and only secondarily upon medical attention when health has broken down. Attention to the factors (1) to (7), so far as is possible and necessary, should precede or accompany any reorganization of medical services."

I should also like to suggest that in Recommendation A, section (i), the unsatisfactory and ambiguous phrase "positive health" be done away with, and that the section might then read: "The system of medical service should be directed to the achievement of the highest pitch of health obtainable, and prevention no less than relief of sickness."

—I am, etc.,

London, N.W.3.

NORMAN A. SPROTT.

Treatment of Septic Hands and Fingers

SIR,—I most heartily endorse all that Dr. E. C. Atkinson has to say on this most important subject (Oct. 2, p. 432). About a year ago we began to run an accident service at the Royal Buckinghamshire Hospital, Aylesbury, modelled so far as possible on the lines of those already inaugurated at the great centres such as Birmingham and Oxford. Although our service leaves much to be desired, there is little doubt that, allowing for wartime conditions, we have achieved much and learned a good deal more. It may be of use to others to enumerate briefly some of our findings.

Whereas fractures, the more severe soft-tissue injuries, and extensive burns are sent to the accident service soon after the receipt of the injury and consequently can be dealt with at once under hospital conditions, septic hands and fingers and the more minor injuries tend to come up much later. Many of these cases have received improper treatment and arrive at hospital with complications, such as bone necrosis, wide soft-tissue destruction, etc., the result of inadequate and late drainage, indiscriminate and ignorant use of fomentations, or faulty incisions. All this means an enormous prolongation of the period of treatment, and often the taking up of a valuable in-patient bed, not to mention the time spent afterwards in rehabilitation.

I should like to point out some of the reasons which account for this rather deplorable state of affairs, which Dr. Atkinson rightly states costs the country a vast amount of time and money in wastage of man-power hours and compensation.

1. Ignorance on the part of the general public, who do not realize the fact that however trivial a finger or hand injury may appear it should be treated with the greatest respect (it may even imperil life) and a doctor consulted. Education on this point is fortunately going forward in the big industrial concerns, where all injuries sustained at work must be reported to the first-aid department. This is a great step forward provided that the right treatment is at once instituted.

2. Avoidance of bad treatment and the institution of correct treatment before the complications which I have already enumerated have had time to set in. To attain this end a better education of the profession in minor surgery is essential. Dr. Atkinson stresses the time taken up in the student's curriculum watching long and complicated operations of a highly specialized nature. While any practitioner should know something of the difficulties associated with major surgical procedures, and of the results of such, in order to be able in the future to advise his patients whether they should undergo this or that operation, far more time should be allowed for the teaching of minor surgery. I think minor surgery is rightly a general practitioner's job provided he has the knowledge, and the general practitioner of the future must be given that knowledge or woe betide the septic fingers receiving treatment in the proposed health centres of the post-war era. The necessary knowledge is sadly lacking to-day, and this is borne out by contrasting the results which can be obtained by careful treatment as compared with those which have received wrong treatment before attending an accident service.

3. Travel in country districts is to-day scanty and expensive, and the poor often find the fares charged beyond their means. It is extremely difficult, therefore, to get patients to attend regularly at the accident service. No doubt the advent of peace and better times will do much to rectify this evil, but it will be some years before an ideal can be attained.

4. Lack of skilled medical personnel. This is the main drawback to-day in the running of any accident service. At least two full-time well-trained casualty officers are essential to run an efficient 24-hour service, and they should be under the direct guidance of one or two general surgeons who are willing to give the necessary time to follow up each case individually. A very large number of septic fingers and other minor injuries can be seen in half an hour, and the necessary instructions with regard to treatment given. This daily visit of a general surgeon has been amply rewarded by the better results obtained at the Royal Buckinghamshire Hospital Accident Service.

5. Accident services should be run by general surgeons, remembering the huge variety of injuries which may result from an accident and that no part of the human body is immune. An orthopaedic specialist to act as consultant is another ideal; he will advise in the more serious problems of injury involving the skeleton. We have an excellent liaison with the Oxford orthopaedic specialists, who attend regularly and, if necessary, in an emergency.

During the months of January to June, 1943, there passed through the Royal Buckinghamshire Hospital Accident Service 69 cases of septic finger with an average attendance of from

CORRESPONDENCE

526 OCT. 23, 1943

10 to 14 days (including what rehabilitation we are at present able to give), 215 new fractures and 987 old, making a total fracture attendance of 1,202. There were 19 minor burns. These figures speak for themselves, as Aylesbury is only a small centre, but if the figures are taken and multiplied for the whole of England some idea can be gained of the magnitude of this problem. Let us hope that the memorandum which Mr. Atkinson so rightly advocates will soon be forthcoming.

—I am, etc.,
Aylesbury

R. H. GARDINER.

Infantile Enteritis and Breast-feeding

SIR.—I have read your annotation on Dr. C. J. McSweeney's report on infantile enteritis and breast-feeding (Sept. 18, p. 367) with great interest. While agreeing with him that breast-feeding, if universally adopted, would materially lessen the prevalence of D. and V. and therefore the death rate among infants, I would point out that until this Utopia is achieved much could be done both in prevention and cure if its aetiology were more generally realized.

D. and V. and dehydration in infants are caused mainly in two ways: (1) by a specific organism which attacks the gastro-intestinal tract; (2) by mastoiditis, which by means of a parasymphathetic reflex floods the intestine (see *Journal*, Aug. 7, p. 168). In both conditions D. and V. and dehydration are the most prominent physical signs. This fact has led to the diagnosis of gastro-enteritis of the faeces proves the absence in which bacterial examination of the faeces is incorrect and that of mastoiditis should be substituted, and such an amide treatment, in spite of dietetic, saline, and sulphonamide treatment, to lose weight, should be handed over to the aural surgeon for surgical treatment, for progressive mastoiditis treated medically is a fatal condition. In this manner many infant lives could be saved, and undiagnosed purulent mastoiditis less frequently discovered post mortem.

It is well known that so-called gastro-enteritis is much commoner in bottle-fed than in breast-fed infants. The main reason for this is that bottle-fed infants, on the other hand, since they are fed sitting up, do not develop mastoiditis through food entering the Eustachian tube. It follows, therefore, that if all bottle-fed infants were fed in the natural position, they, like their breast-fed fellows, would not develop mastoiditis. This important fact should be more universally recognized, by the medical profession, by nurses and mothers, for if universally adopted mastoiditis with its accompanying D. and V. and dehydration would cease to be a common condition.—I am, etc.,

PERCIVAL W. LEATHART.

Birkenhead

Hypersensitivity to Sulphonamides

SIR.—Major R. G. Parks's very informative article draws attention to the dangers of sulphonamides used locally—namely, skin sensitization and possible future complications of oral therapy (July 17, p. 69). I write to describe three cases of local sensitization to these drugs seen in the wards of a hospital, and make some observations on the method and type of sulphonamide application for local use.

Case 1.—Recurrent impetigo of face, mainly affecting the beard area. Treated in unit for three weeks with 30% sulphanilamide cream applied three times daily. On admission, face was slightly oedematous, generally erythematous over areas of application, and some lesions were slightly erythematous and showed vesiculo-papular eruption, especially on the dorsal surface. No other skin lesions.

Case 2.—Mild impetigo of face. Three weeks' treatment in unit with sulphanilamide cream (% not known) applied twice daily. On admission there was an exuding, crusting impetigo of chin and mouth margins and extending as far as the right ear. Apart from the forehead, the whole of the face and neck was erythematous and oedematous. A small area of skin to the right of the neck was weeping and the surface fissured. Erythema and vesiculo-papular eruption present on dorsal surface of hands. Face was sore and the hands itching.

Case 3.—Impetigo of face. Treated with a sulphanilamide ointment (% not known) applied twice daily for seven days. On admission, small-type impetiginous eruption of face, neck, and ears;

mild oedema of face and neck; erythematous-papular rash of the neck and, less obviously, of the face. Marked conjunctivitis the right eye had developed since the treatment had commenced and there was oedema of the right lids. Face sore and slightly itching. No other skin lesions.

Cases 1 and 2 settled with rest in bed, Lassar's paste applied locally at first, and then hydrarg. ammon. 2% in Lassar's. Case 3 responded to rest in bed, eau d'Alibour locally at first, and then a 2% gentian violet lotion. There was no previous history of skin trouble, and it is not known whether they had previously reacted adversely to the drug. Patch, intradermal, and scratch tests were not performed.

It is suggested that in the above cases the type of preparation—ointment or cream—and the frequent application over a long period were determining factors in the production of the reaction. When applied locally a drug has a more intensive action if used either as an ointment or powder than it has in paste form. Where this greater local stimulation exists the possibility of a sensitization resulting is enhanced if at the same time the period and frequency of application be prolonged or high. In paste form the introduction of the drug to the skin is gradual, and the paste itself is both soothing and drying. Briefly, therefore, this would indicate: (1) Where possible employ a paste preparation. (2) Continue the application of the drug only while improvement is being made. (3) Close clinical supervision, including a careful history. In ecchymatous and ulcerative states more use could be made of the "occlusive" type of dressing—the sulphonamide dressing being applied and sealed over and left for a week or longer. For some time I have used a 30% sulphanilamide cream in a base of 60% cod-liver oil and 10% beeswax. This was applied twice daily but discontinued after 6 days on the average. The change to milder but effective preparations of the type of eau d'Alibour was made as soon as possible. Preparations of 30% sul-anilamide and 5% sulphathiazole are now used in a base of Lassar's paste modified to contain 10% cod-liver oil. They have been applied without reaction and with satisfactory results. By the above methods it is anticipated that reactions may be reduced to a very low percentage.—I am, etc.,

H. LEE.
Lieut. R.A.M.C.

Precise Cephalometry

SIR.—I was delighted to read of Dr. Paul Cave's great advance in this procedure (Sept. 18, p. 375). It is based on the recognition of the "greatest circular section" of the foetal head to which I drew attention in my paper (*Proc. roy. Soc. Med.*, March, 1935), and entirely eliminates the personal factor and the small knowledge of obstetrics which were inseparable from the method which I described.

Most reliance should, I think, be placed on the calculation from this circular section, for although the occipito-frontal outline is often most temptingly clear it is impossible to be certain that there is no tilt and that the measurement will not be a trifle low. Furthermore, it is the biparietal diameter which is all-important, and in the case of a brachycephalic head the occipito-frontal might be seriously misleading. It is useful only as a check on minimal size.

For the preparation of the films Dr. Cave's method is extremely simple, and all information on the interpretation of film shadows will be found in my paper. Dr. Elliston's illustrated criticism is, as I pointed out and as Dr. Cave confirms, of no practical importance. It is to be hoped that all radiologists will now become familiar with this simple and reliable technique, and that obstetricians will make full use of it. Dr. Cave is greatly to be congratulated on an important advance.—I am, etc.,

NORMAN REECE.

Brixham, Devon.

Vitamin E and Menopausal Flushes

SIR.—I have just seen the article by Hain and Sym in your issue of July 3 in which some observations on the influence of vitamin E upon menopausal flushes are recorded. As a remark of mine at the vitamin E symposium in 1939 appears to have provided the original stimulus to this investigation, I may perhaps be pardoned for offering some comment. I have been impressed for years past by the numerous studies in the literature tending to show that post-menopausal patients frequently excrete appreciable amounts of oestrogenic substance. My own studies have amply confirmed the fact that

such women often exhibit oestrogens in quantity in the blood, as others have also found. I have recently tried to call attention² to this point in the effort to explain the not infrequent failures of oestrogenic therapy in menopausal states. Indeed, everyone must have seen patients definitely worsened by such treatment. Believing as I do that vitamin E is a potent anti-oestrogen, it seemed worth while to administer it to menopausal women. The relief of hot flushes and the troublesome headaches of this epoch was early observed, and was commented on in a paper read before the Toronto Academy of Medicine in 1937.³ The observation has never seemed to attract attention because the whole gynaecological world appears to be quite convinced that oestrogens are the *sine qua non* at the climacteric.

May I say that I rarely use oestrogens for menopausal disorders, that I have treated scores of such women with vitamin E, and that I believe my results would compare favourably with those of physicians who use oestrogens. There is little point in offering a statistical analysis of my cases, since, if Dr. Hain's suggestion is followed, others will try this remedy promptly and come to their own conclusions. I usually try 10 mg. of ephynal as a daily dose for 7 to 10 days, and, if that fails, at once increase the dose to 25 mg. per day for a time, reducing it later as indicated.

I notice that Hain and Sym found that vitamin E helped a woman with vulvar pruritus. Such patients usually require huge daily doses (100 mg. ephynal or even more), exhibit no changes for a latent period of at least 10 to 14 days, but then many obtain striking relief and visible rejuvenation of the vulvar tissues.² Oestrogens not infrequently render the discomfort of these women intolerable. May I very earnestly recommend a trial of vitamin E for such unfortunates.—I am, etc.,

London, Ontario.

In Defence of Nursery Schools

SIR,—As a nursery-school teacher I have been much disturbed by the debate on State nurseries which was reported in your issue of July 17. I feel that Dr. Helen Mackay has been singularly unfortunate in the nurseries she has visited, in which she found "a good deal of shouting from tired women, and crying from fretful children"; also in which there was a high incidence of infection and a low incidence of happiness. These facts are not typical of nursery schools, in which I have worked for the past 14 years. Surely Dr. Brodie has put her finger on the seat of the trouble when she declares that physical health is the first consideration, and mental health only comes second. Surely, also, Dr. Back discards the remedy for unhappy nurseries by stating that nurseries should not be developed as part of our educational system?

Nursery schools are playing a great part in our plans for education. They are in charge of teachers fully qualified to deal with the physical, mental, emotional, and social needs of children aged 2 to 5 years. The day's routine is carefully planned so as to provide all the essentials conducive to the health and happiness of the children. Various types of occupation and activity give ample scope for their all-round development; there are no periods in which they "do nothing." Each child is treated as an individual, with a personality which is recognized and respected by the staff. The food is well balanced and attractive and there is a rest period during the day. When the weather is at all suitable the children are out of doors as much as possible, having meals, sleep, and play in the garden, thus securing the maximum amount of fresh air and sunshine. We have found that our children keep fit and gain weight steadily after admission to the nursery. Home food problems and temper tantrums gradually die away, and we have a group of happy contented children, and appreciative mothers with whom we are in close and constant touch. I would like to add on behalf of those mothers that I have visited many of their homes, and I have a great admiration for the way they are working. Many are doing full-time work, and in very few has the home lapsed into squalor—granted there are some women who neglect their homes, but this is

not chiefly owing to the fact of their being out at work. They are the ones who would be slovenly under any circumstances, and the ones who struggle hopelessly under bad housing and social conditions; and they are becoming a small minority.

May I suggest that, in order to improve matters in wartime nurseries, the Ministry of Health should seriously consider the advisability of giving more financial support for the provision of educational equipment, play with which will satisfy the natural urges of the child.—I am, etc.,

B. R. ABELSON.

Fractured Great Toe

SIR,—Dr. G. N. Taylor (June 12, p. 724) draws attention to the fact that fracture of the great toe is the commonest fracture in industry. Seven years of experience as an industrial medical officer has convinced me that the incidence of this injury can be greatly reduced by the use of "safety boots."

As Dr. Taylor points out, trephining the nail gives dramatic relief from the pain due to subungual haematoma. I have found that the best instrument for this purpose is an ordinary twist drill of small diameter. These drills are always available in engineering workshops; they are easily sterilized by boiling; and, being designed for cutting holes in hard surfaces, they will cut through a nail with far less discomfort for the patient than an operating knife, which, after all, was designed for an entirely different purpose. The method of operation is to rotate the drill gently between thumb and index finger.—I am, etc.,

H. M. L. MURRAY.

Controller of Welfare, Department of Labour and
National Service, Melbourne, Australia.

Food for Nurses

SIR,—Commenting on the recent revelations respecting hospital food, a surgeon writes me: "Who would send their daughter into nursing with things as they are?" Exactly. Posters depicting beautiful girls in uniform will not allure till parents realize that hospital conditioning has been everywhere upgraded. Here and there feeding may be above reproach, but its generally low reputation, in relation to output of energy demanded, is now shown to be well founded.—I am, etc.,

Moor Park.

ESTHER CARLING.

Aleukaemic Myeloid Leukaemia

SIR,—I was much interested in the article by Dr. Della Vida and Mr. M. C. Connell (Oct. 2, p. 417). The first case described bears certain resemblances to one that I saw and investigated about ten years ago. My notes on the case are hard to come at at the moment, but to the best of my recollection the particulars were as follows. It will be seen that they present several features of considerable interest.

The patient was a solicitor, who stated that whenever he was overworked in the course of two or three years before the onset of his present illness a crop of haemorrhagic spots appeared on his shins, but these faded if he took a holiday. No blood count had ever been made. On examination his mental and general clinical features were very like those described by Dr. Della Vida, but his spleen was palpable though not very large. His total white count was in the vicinity of 5,000, and the differential count showed practically the same features as those in the count described in the article. Further counts were made at intervals of a week, and later at intervals of a fortnight. The patient improved clinically, but his white count rose steadily and continuously to 111,000 at the end of about eight weeks, the increase being accounted for by an increasing proportion of very rudimentary cells, identifiable only with difficulty as very immature myeloid cells.

At this stage the consultant for whom I was working handed him back to his G.P., who called in his own pathologist. I was stupefied to get a note from him about a fortnight later to say that the patient's blood count was now normal, and that he was very much better. I may say that he had had no treatment, and the doctor's letter ended with the ominous note that he now had some free fluid in his abdomen. I met the other pathologist and compared notes and blood films with him, and I don't think we were either of us surprised to hear that the patient had died a fortnight later. No P.M. was possible

OBITUARY

One is tempted to wonder, judging from his history, whether he had been having periodic spells of aleukia with haemorrhages, followed by rising counts of myeloid cells, during the whole of the two or three years that the purpura had been noticed. I should be very much interested to hear whether there is any evidence that such a thing can happen spontaneously. I had previously always imagined that the aleukias one saw were the terminal phases of leukaemias, the bone marrow having finally thrown in its hand, and was surprised to find that here it had managed, without outside help, to pick up again, possibly on quite a number of occasions.—I am, etc.,

J. W. SHACKLE.

Haywards Heath.

The Common Cold

SIR,—Dr. E. W. Braithwaite's letter (Oct. 2, p. 433) is of interest, but it is necessary to know what is his criterion of "cold." Is it merely a running at the nose, or does he require the presence, in addition to the running nose, of the usual constitutional disturbances, however mild, associated with the common cold and indicative of its infective origin? If, as one suspects, the former is the case, then the condition which he describes is that of vasomotor rhinitis (paroxysmal rhinorrhoea), a vasomotor neurosis. It is, of course, incorrect to be influenced by emotional factors. It is, of course, incorrect to describe vasomotor rhinitis as in any way being a cold, though the layman may find it impossible to distinguish between the two, and will refer to it as such if he is himself a sufferer. The question of diagnosis may account for Dr. Braithwaite's astounding contention that the specific factor in the common cold "is psychological, the microbe is at present so muddled that it would seem a great pity unnecessarily to allow confusion to become worse confounded.—I am, etc.,

BASIL M. MERRIMAN.

London, S.W.1.

Obituary

CECIL ROWNTREE, F.R.C.S.

Consulting Surgeon, Royal Cancer Hospital
We regret to record the death of Mr. Cecil Rowntree, which took place, after an illness of two years' duration, at his home East Grinstead, Sussex, on Oct. 9. He was in his sixty-fourth year. For a quarter of a century or more he had been recognized as a surgeon of exceptional skill and resourcefulness, specially of late years in the field of proctology. He was an enthusiastic captain in the fight against cancer, and not only by his own clinical observations and surgical procedure but by his encouragement of other workers in wider research he had done as much as any man in his time to assist the progress of operations along this extended front.

Cecil William Rowntree was the son of a London doctor, W. G. Rowntree, and was born in 1880. He was educated at University College, London, and went on for his medical training to Middlesex Hospital, where he held the Murray scholarship in 1901 and the Freeman and Hetley scholarships in obstetrics and in clinical medicine and surgery in 1902. He qualified with honours in medicine in that year, and took the F.R.C.S. in 1905. It was the Middlesex, even in those early years of the century, which directed his interest in the experimental methods, which research he was registrar in the cancer wards of the Royal College of Surgeons; this was also the first year of Sir Arthur Keith's Hunterian professorship of surgery to the Royal College of Surgeons; this was also the first year of papers were coming from Rowntree's pen, testifying to his alertness with regard to all that had to do with cancer. These appeared in the *Surgical Reports of Middlesex*, of which he was the editor in the years 1909-11. He also contributed the section on the treatment of cancer to Latham and English's *System of Medicine*

in 1912, and in the same year he edited C. H. Leaf's *Cancer of the Breast Clinically Considered*, a new edition of a work which had been published eight years before. Although later on he was known largely as a proctologist, these early studies covered a wide range—cancer of the lip and tongue cancer of the breast, x-ray carcinoma, among others.

For many years Rowntree was on the surgical staff of the Royal Cancer Hospital, Fulham Road, ultimately becoming its senior surgeon. He retired three years ago at the age of 60 and became consulting surgeon to the Woolwich and District War Memorial Hospital. Other hospitals with which he was associated were the cottage hospitals of Caterham, Erith, and East Grinstead. At one time he was a member of the surgical staff of the Dreadnought Hospital. During the war of 1914-18 he served in the R.A.M.C.(T.), reaching the rank of brevet major. He was also consulting surgeon to the American Red Cross.

His death will be severely felt in the ranks of the British Empire Cancer Campaign, an organization to which he gave his best energies. He was a member of its grand council and of its executive and clinical research committees. He took a large share in the arrangements of the biennial informal conferences of cancer workers from all over the country which were organized by the Campaign, and of the last of these, held in 1939, he was vice-chairman. He seldom came into the limelight, but his was the hand very largely directing the proceedings. At the council table he was seen at his best entering fully into the exchange of information and experience and both wise and modest in what he put forward. He vied not in its progress which the various investigators were making on physical and chemical lines. His reputation as a pioneer whose methods had been tried out and incorporated in general surgical practice extended beyond this country. He was honorary secretary of the surgical section of the International Conference on Cancer held in 1928, and he represented Great Britain in the Union Internationale Contre le Cancer, of which he was vice-president and a member of the executive. For his work in international surgery he was made Officier de l'Ordre de Léopold and Chevalier de la Légion d'Honneur. He served as president of the Subsection of Proctology of the R.S.M.; he was also a Fellow of the British Association of Surgeons, and in the B.M.A., which he joined in 1909, he was chairman of the Westminster and Holbo Division in 1928-9.

Rowntree was a man of fine build, in earlier years an athlete of distinction, a member of the Ranelagh Club, and an expert golfer. He had also a singularly handsome and dignified appearance, but one which indicated the kindness of his nature. He was always a most likeable man, more interested in the patient than in the case, and most mindful of his colleagues and assistants, whose confidence he enjoyed to an exceptional degree. He married in 1908 Katharine Aylmer, daughter of the late Mr. H. Whitworth Jones, and had two sons and one daughter. Among his surgical colleagues and a host of workers on cancer the news of his death will come with a sense of personal loss.

An old friend and colleague writes: The death of Cecil Rowntree at the age of 63 closes a long and gallant struggle against a cardiac disability which had limited his activities for very many years. Many and many a time he carried through exhausting programmes of operations in hospital at the cost of an oedema which would have made a less resolute fighter cry quits. In everything he did a vivid personality, an acute brain, and a strong sense of humour—one of the half-dozen among the medical profession in London, certain He had, as his record testifies, administrative ability of a high order besides his gifts as a surgeon. He was too quick in the uptake himself to suffer fools gladly, but only occasionally did he allow irritation to be discerned. Before his hair thinned it was of an arresting shade of red, which has been inherited by some of his family. He leaves a widow, two sons—one of whom is doing well in his father's profession—and a daughter.

G. H. EDINGTON, F.R.C.S.

An intimate friend writes:

While your obituary notice of George Edington supplied a record of his appointments and public work, both it and the delightful appreciation from a fellow member of the Moynihan Club leave much that might be said concerning his many-sided character. All his life he was interested in anatomical and embryological problems, and many of his writings were either in these fields or dealt with their bearing on surgery. I first remember him at the Oxford Meeting of the B.M.A. in 1904, when he read a paper on cysts in the neck, a subject with which his name was already associated. The thesis he presented for the D.Sc. in his own university had the same bent and was entitled "Congenital Occlusions of the Oesophagus and Lesser Bowel." In all that Edington said or did he was transparently honest, and professional integrity was his watchword. I well recall a contribution which he made at the Dublin Meeting of the Association. The subject was the surgical treatment of gall-stones, and he had to relate an unusually high mortality among his patients, but there was no attempt to explain away or gloss over unpleasant facts, and his only concern was to discover an adequate reason, and this was always his attitude towards his work. Edington had profound faith in his profession and confidence in its future, and his advice and encouragement were often helpful to young entrants, whom he was never tired of helping. Though very loyal to the Western he loved the old Glasgow Royal, and the short address on "The Soul of a Voluntary Hospital," delivered in 1931 before a lay audience at this hospital, was self-revealing and appeared to touch the very core of the subject. His early association with Macewen in the old Royal made a lasting impression, and many were the stories he had to relate of those strenuous days. Edington was a man of culture and was especially fond of books, history and biography being favourites. Though he was not a ready linguist he was deeply interested in language, and etymology was one of his hobbies. He was well versed in the story of his own city, and it was delightful to prattle about the old places in his company, for there were few he could not surround with lore and anecdote. The history of surgery was another interest, and he was well versed in the story of the Listerian period in Glasgow. In 1928, when president of the Medico-Chirurgical Society, he had erected a very suitable memorial to Lister in the rooms of the Society, incorporating a fireplace from Lister's accident ward presented by J. H. Teacher, and a plaque of the master presented by Sir Hector Cameron.

Edington was very fond of travel, and those privileged to be among his companions always had their journey enriched by his knowledge of the history of the places visited and the story of the people. The pleasures with which he could smooth over those little inconveniences incidental to travel, even in the luxurious days before the war, were always refreshing. His bearing in audience with the Pope, in conversation with Queen Ena of Spain, or at a reception in the Palace at Warsaw were occasions to be remembered. For the writer the happiness of the last meeting of the International Surgical Society which took place in Brussels in 1938 was largely connected with Edington and his sage observations in keeping with the atmosphere of those ominous September days. No one had a greater gift for cordiality, and he loved to keep his friendships warm, often by delightful letters, a timely reprint, or a present of some book of mutual appeal. He was most generous, and never so happy as when entertaining his intimates. He had quite a flair for creating an occasion, as those of us knew who were his guests in Glasgow, and he thoroughly understood the art of making one feel comfortable and welcome among his friends.

G. G. T.

CHARLES GIBBS, F.R.C.S.

Mr. Charles Gibbs, consulting surgeon to Charing Cross Hospital and for many years senior surgeon to the London Lock Hospitals, died suddenly at Thames Ditton Cottage Hospital on Oct. 5 aged 75. He was well known as a specialist in genito-urinary surgery and venereal diseases.

He was born in London, and entered as a student at Charing Cross Hospital in 1885, where after qualifying in 1890 he held all the minor appointments, including that of surgical registrar. He took the F.R.C.S. in 1893, and was for a time superintendent of dissections for the Royal Colleges. In 1896 he was elected assistant surgeon to Charing Cross Hospital, and later became surgeon in charge of the venereal disease department, lecturer on clinical surgery and anatomy, and vice-dean of the medical school. In the early part of the South African War Mr. Gibbs served as senior surgeon to the Langman Field Hospital; during the last war he held a commission as temporary major R.A.M.C.(T.) in charge of beds at No. 4 General Hospital. He wrote a number of articles on gonorrhoea and other diseases of the male reproductive organs for *Quain's Dictionary of Medicine*, and was one of the first in this country to report the results

of treatment of syphilis by French and English substitutes for salvarsan. He had joined the B.M.A. as long ago as 1892, and was vice-president of the Section of Venereal Diseases at the Newcastle Annual Meeting in 1921.

Mr. J. JOHNSTON ABRAHAM writes:

Having secured many scholastic honours as a student Charles Gibbs proved an active and popular lecturer at the Medical School of Charing Cross Hospital, and finally retired in 1923, by that time having become senior surgeon. He was elected assistant surgeon to the London Lock Hospitals in 1897, and full surgeon in 1907, and was still in active work there as senior surgeon at the time of his death, a period of forty-six years of service to this old charity which is probably unique. In 1899 he volunteered for service in the Boer War and was attached as senior surgeon, with the rank of captain, to the Langman Hospital, having Conan Doyle as a medical colleague. In the 1914-18 war he served as a Territorial officer, receiving in 1919 a letter of thanks from the General Officer Commanding London District for "his valuable and devoted work at the 4th London General Hospital during the past four years." He became a member of the *Pewterers Company* in 1889, and served as its Master in 1928. Gibbs was a magnificent teacher. His classes for the finals in surgery of the College and London University were always crowded. Many old Charing Cross men will remember with gratitude the clear coaching on essentials they obtained from him, for he was a master of exposition. A man of retiring and modest disposition, he was entirely wrapped up in his professional pursuits and family life. He never quite recovered from the death of his wife in 1940; and he now leaves a son and daughter who, though mourning their loss, are devoutly thankful that, having worked all his life to relieve the sufferings of others, he was spared himself from the trials of a lingering illness.

The sudden death of Dr. RONALD MACKINNON at Oldham on Aug. 31 came as a shock to a wide circle of friends and patients. Born in 1881 in the village of Staffin in the Isle of Skye, he was educated at Inverness Academy and qualified from Glasgow University, M.B., Ch.B., in 1904. Thereafter began his long training for the competent all-round physician he later proved himself to be. Besides assistantships he held resident appointments in Oakbank and Duke Street Hospitals, Glasgow, Islington Infirmary, Sheffield Royal Infirmary, and Leeds City Fever Hospital. Having joined the R.A.M.C. Special Reserve shortly after qualification he was only three months settled in his Oldham practice when he was called up in August, 1914. He served in France till the end of the war. When he returned to Oldham and resumed his practice it soon began to increase, and continued to increase until the attempt to cope with the work, latterly single-handed, overtaxed his strength and shortened his days. From 1920 on he was honorary pathologist to Oldham Royal Infirmary, and he published articles including "Post-mortem Findings in a Case of Exophthalmos" and "Rupture of Aortic Aneurysm in a Young Woman." His interest in the military aspect of the profession did not cease with his age-retirement as major, R.A.M.C., S.R. When the Home Guard was formed he joined up again and became the M.O. of the local unit. A busy professional life did not leave much leisure for the cultivation of hobbies, but Ronald Mackinnon was a keen student not only of the history of his clan, of whose military and ecclesiastical attainments he was so proudly proud, but also of the language, literature, and music of the Highlands. When in 1930 a Manchester branch of the *Comunn Gaidhealach* was formed, he was unanimously elected its first president, and to the end its interests were very near his heart. But his professional work always came first. Endowed with a pleasant manner and a quiet wit that never wounded, of the highest personal character, popular with his colleagues, skilled, conscientious, and painstaking, he was an ideal family practitioner, trusted alike as physician and counsellor. The affection in which he was generally held was shown on the day of the funeral service by the overflowing congregation and by the crowds which lined the streets. He was buried in his native Isle of Skye, where he rests in the shadow of the hills which he loved so well.—N. M.

With the death of Dr. FREDERICK MACPHERSON TRAILL SKAE there has passed away a member of a family who made their mark upon mental science in former generations. Dr. Skae was a grandson of the late Dr. David Skae, physician-superintendent of the *Royal Morningside Asylum*, Edinburgh, who introduced into that institution many reforms and ideas new in his day. His father, the late Frederick W. A. Skae, Inspector-General of Asylums and Hospitals, New Zealand, organized the mental hospitals and afterwards the general hospitals of the Dominion. Dr. F. M. T. Skae was for some time assistant to the late Sir John Macpherson in the *Stirling District Mental Hospital*, and later went to the *Federated Malay States*, where he spent some years as a general practitioner. He

OBITUARY

530 OCT. 23, 1971

returned in Scotland and served during 1914-19 in the Orkney R.G.A. In 1922 he was appointed assistant to Prof. Yule Mackay at University College, Dundee, and to Prof. Rutherford Dow, a post which he held until 1941.

Dr. J. N. LEGGE PAULLEY died on Sept. 1 at Cheltenham, where he had lived since retiring from active work in 1922. He was born at Tollard Royal, Wilts, on Dec. 22, 1855, and was educated at Westminster Grammar School and St. Bartholomew's Hospital; he qualified M.R.C.S. in 1877 and took the L.R.C.P. Ed. in the following year. He then went to practise at Pulham Market, Norfolk, and was medical officer for the 4th District of the Deepwade Union from 1883 to 1919, in which year he was made a J.P. for the County of Norfolk. Dr. Paulley joined the B.M.A. in 1883 and remained a member after his retirement. He had always been on good terms with his colleagues in Norfolk and liked to meet other medical men socially at the monthly meetings of the Gloucestershire Branch. Almost to the end of a long life he made a point of reading the B.M.J. every week. His recreations were gardening and chess.

The medical profession in the West Riding, and especially of Keighley, has lost an outstanding personality by the death of Dr. J. E. H. SCOTT on Sept. 7. He studied medicine at Leeds and graduated M.B., Ch.B. Vict. in 1899. On his retirement from active service in 1936 Dr. Scott, by that time honorary consulting surgeon to the Keighley Victoria Hospital, was presented with a wallet and a cheque of appreciation of his services of the Keighley district, in token of appreciation of that given during 21 years as their representative on the West Riding Panel Committee. He was then co-opted as a member of that committee, which had always greatly appreciated his opinions and suggestions. Dr. Scott joined the B.M.A. in 1912, was chairman of the Bradford Division in 1924-5, and served for two long periods on the National Formulary Subcommittee at headquarters. When war came he emerged from retirement to relieve the pressure upon his colleagues.

We regret to record the death on Sept. 8 at his home in Stanley, Perthshire, of Dr. ROBERT BURGESS, who was for many years a staunch and active worker for the British Medical Association. He studied medicine at the University of Aberdeen, graduating M.B., C.M. in 1893, and after holding posts as clinical clerk in the ear and throat department of the Edinburgh Royal Infirmary and in general practice at Stanley, Huddersfield Infirmary set up for the Parishes of Kinclaven where he became medical officer for Auchtergaven, M.O. and Moneydie, joint medical officer for surgeon. Dr. Burgess to the Post Office, and certifying his Division at the last joined the B.M.A. in 1900, represented the Perth Branch in Glasgow Meeting, and was president of the Perth Branch in 1922-4. From 1937 to 1940 he was a member of the Scottish Committee.

We regret to announce the death of Dr. GEORGE HENRY PATTERSON on Sept. 12, within a few days of attaining his eighty-seventh birthday. Born on Sept. 14, 1856, he received his medical education at St. Bartholomew's Hospital, taking the M.R.C.S. and L.R.C.P. in 1879 and the D.P.H. in 1896. After holding various house appointments at St. Bartholomew's and elsewhere he settled in Dalton-in-Furness, where he engaged in general practice. In 1886 Dr. Patterson became part-time M.O.H. of the Dalton Urban Sanitary District and in 1898 whole-time M.O.H. of the Ulverston Combined Sanitary District, comprising the Urban and Rural Districts of Ulverston and the Urban Districts of Dalton and Grange-over-Sands, with a combined population of some 43,000 and an area of no less than 56 miles. Thus he acted as M.O.H. for a period of no less than 56 years. It is given to few men to hold office for such a long period, yet Dr. Patterson made the most of his opportunities and continued to render active service up to the very end.

We regret to announce the death on Sept. 14 in Kensington of Dr. HANNAH PERRY ANDERSON, widow of the late Prof. Richard John Anderson, M.D., of Queen's College, Galway, and Newry, Co. Down. She was the daughter of the late Samuel Perry of Belfast, and received her education at Victoria College, Belfast, and at the Richmond Hospital, Dublin. She graduated B.A., M.B., B.Ch. of the National University of Ireland in 1918. Her first appointment was that of assistant resident physician at the Bermondsey Medical Mission. She was appointed in 1923 medical registrar at the London Temperance Hospital and M.O. to the ante-natal clinic, Archer Street Welfare Centre. Dr. Perry Anderson joined the B.M.A. immediately after qualification and served as a Representative at thirteen consecutive Annual Meetings, the last being in Aberdeen in 1939.

The Services

CASUALTIES IN THE MEDICAL SERVICES
Died at Sea.—Fl. Lieut. K. W. Monks, R.A.F.V.R.
Wounded.—War Subs. Capt. G. Byrne, R.A.M.C.

DEATHS IN THE SERVICES

Surgeon Rear-Admiral Sir THOMAS DESMOND GIMLETTE K.C.B., R.N., died on Oct. 4 at Epsom shortly before attaining the age of 86. He belonged to a family with naval traditions, for his father was Fleet-Surgeon Hart Gimlette, R.N. (the Navy List of just before the present war shows the name of Surgeon Commander C. H. M. Gimlette, who may also belong to the same family). Thomas Gimlette was educated at St. Thomas's Hospital, qualified in 1878, and held many important posts in the Navy, including charge of the Royal Naval Hospital in Hong Kong in 1904-7, and of the Haslar Royal Naval Hospital 1908-11; he retired in 1913. He saw active service in Egypt in 1882, in the Sudan in 1884, was mentioned in dispatches, and received two medals and two clasps. He was medical officer to an admiral during a mission to Abyssinia in 1884. In 1887 he was promoted to be Deputy Inspector General, Hospitals and Fleets. On the outbreak of war in 1914 he returned to active employment as Admiralty recruiting officer at headquarters. He was made a C.B. in 1907 and advanced to K.C.B. in 1911. He thus had a long and distinguished career and lived to enjoy a well-earned retirement. He was twice married, and by his first wife he had two sons.

Medical Notes in Parliament

Sir ERNEST GRAHAM-LITTLE was elected chairman of the Parliamentary Committee in succession to the late Sir Frank Fremantle at a meeting of the committee on Oct. 13.

The A.R.M., the Government, and Assumption B

Sir E. GRAHAM-LITTLE inquired on Oct. 14 whether the Minister of Health knew that the Representative Body of the B.M.A. had, in 1942 and 1943, recorded almost unanimous opposition to the establishment of any whole-time salaries for the State Medical Service and to the extinction of private practice as proposed in Assumption B of the Beveridge report; that similar opposition had come from numerous plebscites of the profession; and whether he still adhered to his declaration at Westminster Hospital on Oct. 4 that the Government had accepted Assumption B and was engaged in putting its provisions into operation. Mr. ERNEST BROWN said the answer to the last part of the question was "Yes." If Sir Ernest would look again at Assumption B he would find that it did not contain the particular proposal which he described, nor did it purport to deal at all with the method of organizing the new service. Mr. Brown added that he had never said the matter had been determined already and that it was being put into operation.

Dr. RUSSELL THOMAS remarked that 90% of the profession had already turned down the matter.

Representative Committee's Discussions

Sir E. GRAHAM-LITTLE also asked on Oct. 14 whether before publishing the promised White Paper on health services Mr. Brown would afford opportunity to the committee appointed at his request to represent the medical profession to discuss these services, not on the basis of any preconceived plan, but from the ground, in accordance with the undertaking given to him in these terms in March, 1943, which had not hitherto been kept, and the continued breach of which had caused resentment in the medical profession. Mr. BROWN said he could not accept this version of what had so far taken place. He intended to adhere to the procedure which he announced at the outset.

Ophthalmic Research at Oxford

On Oct. 12 Mr. THORNE asked the Financial Secretary to the Treasury whether the Government proposed to give a grant towards the £250,000 research station to be built at Oxford for eye research. Mr. ASSHETON said he had seen the public appeal recently made for £250,000 to build, equip, and endow the research laboratories of a Department of Ophthalmology at Oxford University. No question of Government aid towards the cost of this scheme had been raised; if it were it would no doubt have to be considered along with the other post-war needs of the universities.

Serving Doctors and the White Paper

Dr. RUSSELL THOMAS asked what steps Mr. Brown had taken to ascertain the views of doctors serving in the Armed Forces in this country and abroad on the future of medical practice. Mr. BROWN answered that he was alive to the need for this, but the appropriate time would be when the White Paper had been issued as the basis for public discussion. Dr. RUSSELL THOMAS suggested that no steps had been taken to ascertain the views of about 30,000 doctors connected with the Armed Forces. Dr. SUMMERSKILL asked whether Mr. Brown had taken advice only from the older doctors and not from the younger ones in the Services. Mr. BROWN repeated that the proper time would be when the White Paper was before Parliament.

Treatment of Leprosy in Central Africa

On Oct. 12 Sir E. GRAHAM-LITTLE asked the Parliamentary Secretary to the Ministry of War Transport if he was aware that the universities mission to Central Africa had been frustrated in the treatment of leprosy by the lack of essential drugs from India, which were held up by shipping restrictions, resulting last year in the closure for from four to seven months of all centres conducted by the mission. Mr. NOEL BAKER said that the drug in question was hydnocarpus oil, supplies of which had hitherto been obtained by the mission from local medical officers in Tanganyika Territory. Recent inquiries addressed to Tanganyika Territory showed that supplies of this oil were now being received from India and were now adequate. He had no information in support of the suggestion that the difficulties last year were due to shipping.

Hospital Accommodation in African Territories

Mr. EMRYS-EVANS informed Major Lyons on Oct. 12 that the numbers of beds available for Africans in Government hospitals in the High Commission Territories were: Basutoland 254, the Bechuanaland Protectorate 128, and Swaziland 44. The ratio of beds to population was 1 to 2,600 in Basutoland, 1 to 2,076 in the Bechuanaland Protectorate, and 1 to 3,483 in Swaziland. If the beds available in the mission hospitals, most of which were Government-grant-aided, were included, the ratios were 1 to 2,000, 1 to 1,067, and 1 to 1,783 respectively. Plans for the further development of the medical services in the three Territories, to be undertaken as soon as conditions allowed, were being considered.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of scarlet fever rose by 184, of whooping-cough by 103, of acute pneumonia by 53, and of dysentery by 67. Those of diphtheria fell slightly by 33 cases, and there was one case fewer of measles than in the preceding week.

For the sixth consecutive week there has been a steep rise in the incidence of scarlet fever, this being higher during the past quarter than in any recent third quarter. The largest increases during the week were in Yorks West Riding by 34, in Middlesex by 31, in Warwickshire by 26, and in London by 22 cases; the only drop of any size was in Lancashire, by 27 cases.

The local distributions of measles, whooping-cough, and pneumonia remained fairly constant. The largest variation in the trend of diphtheria was a decrease in Lancashire by 36.

In Scotland notifications of scarlet fever rose by 44, diphtheria by 25, and measles by 11; those of whooping-cough fell by 27. The incidence of dysentery was lowered for the fourth consecutive week, but the disease was still widespread; 62 cases were reported from nineteen areas, the most important centre of infection being Glasgow with 15 notifications.

Dysentery

Recent notifications of dysentery have been high. The 337 cases recorded this week constitute the largest total for any week since Dec., 1937. Notifications for the past seven weeks number 1,736. During the corresponding periods of 1939 and 1938 there were 208 and 234 cases. The largest rises during the week were in London from 42 to 91—Lambeth 39, St. Marylebone 10 (the remaining cases were contributed by eighteen boroughs). In Kent the returns went up from 36 to 57—Gravesend M.B. 21, Rochester M.B. 10, Maidstone R.D. 12; in Essex, notifications rose from 7 to 33 (Walthamstow M.B. 29), and in Lancashire from 15 to 42 (Blackburn C.B. 11, Prestwick M.B. 13).

The Week Ending October 9

Notifications of infectious diseases during the week in England and Wales included: scarlet fever 3,249, whooping-cough 1,481, diphtheria 732, measles 581, acute pneumonia 557, cerebrospinal fever 30, dysentery 263, paratyphoid 8, typhoid 9.

No. 39

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Includes paratyphoid A and B.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Oct. 1 Dr. J. A. Venn, President of Queens' College, resigned the office of Vice-Chancellor, and Dr. F. Shirley Hele, F.R.C.P., Master of Emmanuel College, was admitted to the office for the year 1943-4. The outgoing Vice-Chancellor in the course of his address to the Senate referred to the vacation by Dr. John A. Ryle of the Regius Chair of Physic on appointment to the Professorship of Social Medicine at Oxford, and wished him every success. It had been hoped, he said, that, despite grave difficulties arising from war conditions, at least two or three more appointments to vacant Professorships could have been effected, but circumstances arose that made postponement necessary. "I would, however, express the strongest hope that further elections will be made in the coming year, for it is really essential that certain large and very active departments associated with some of the 17 chairs that are now vacant should be thus strengthened. Foremost among them I would place the department of medicine, which is so closely involved not only with the proposed regionalization (or, dare I say, nationalization?) of the profession but also with the status of Addenbrooke's Hospital. The appointment of a successor to Dr. Ryle would, on all grounds, be most welcome." Finally, in welcoming the incoming Vice-Chancellor he said of Dr. Hele: "He comes into office at such a turning-point in the world's history that—it seems almost certain—to him must fall the opportunity of guiding the University in the difficult days of reconstruction and expansion. Possessing all the essential qualities of heart and of head, he carries with him our best wishes for the successful outcome of that great task."

Dr. A. C. Chibnall, F.R.S., the new Sir William Dunn Professor of Biochemistry, has been elected into a Professorial Fellowship at Clare College, and Dr. R. A. Fisher, F.R.S., Arthur Balfour Professor of Genetics, has been elected into a Professorial Fellowship at Gonville and Caius College, of which he is a former Fellow.

A course of eight lectures on "Science in the Sixteenth and Seventeenth Centuries" will be given on Saturdays at 12 noon during next Lent term. Details will be announced later in the *University Reporter*. These lectures are open without fee to all members of Cambridge and London Universities or of Girton and Newnham Colleges.

Medical News

The subject of Miss Margery Fry's Chadwick Lecture, to be given at the London School of Hygiene and Tropical Medicine, Gower Street, W.C.1, on Oct. 26 at 2.30 p.m., will be "Ill-health and Ill-being."

Dr. J. W. Brown will give the Bradshaw Lecture at the Royal College of Physicians on Nov. 4 at 2.15 p.m., and his subject will be interauricular septal defect.

Dr. H. S. Souttar, C.B.E., F.R.C.S., will deliver the Bradshaw Lecture on "Physics and the Surgeon," at the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on Thursday, Nov. 11, at 3.15 p.m. Students and others who are not Fellows or Members of the College will be admitted on presenting their private visiting cards.

At a meeting of the Medico-Legal Society to be held at Manson House, 26, Portland Place, W.1, on Oct. 28, at 4.30 p.m., a joint paper will be read by Dame Louise McIlroy and Mr. D. Harcourt Kitchin on "Medico-Legal Problems in the Treatment of Venereal Diseases."

A meeting of the Eugenics Society will be held on Tuesday, Oct. 25, at 5.30 p.m. in the rooms of the Royal Society, Burlington House, Piccadilly, when Dr. A. Spencer Paterson will speak on "The Size of the Family of the Business, Professional and Titled Classes," with Lord Horder in the chair. Further meetings will take place on Nov. 16, Dec. 14, Jan. 18, and April 18, at the same time and place.

The centenary meeting of the Royal Anthropological Institute will be held on Saturday, Oct. 30, at 11.15 a.m., at the Royal Society, Burlington House, under the presidency of Prof. J. H. Hutton. C.I.E., D.Sc. Sir John L. Myres will give the opening address on "A Century of Our Work." Lord Hailey will give an address on the role of anthropology in colonial development, at 1.30 p.m. At 3 p.m. the future of anthropology will be discussed at the Royal Anthropological Institute, 21, Bedford Square, W.C.1, by Mr. G. M. Morant, D.Sc. (physical anthropology), Prof. V. G. Childe (archaeology), Mr. R. U. Sayce, M.Sc. (material culture), and Mr. R. Firth, Ph.D. (social anthropology).

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (from 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Antiology* Westcent, London; SECRETARY, *Mediscra* Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Putrefactive Dyspepsia

Q.—What is a probable cause of stools (in a male of late middle life but otherwise fairly healthy) being chronically for a year or two past of the consistency of adhesive clay (but of normal, not "clay" colour), and therefore causing a daily and troublesome difficulty in evacuation? There is a general lack of "tone" throughout the body, but how does this affect—if it does—a deficiency in natural lubrication of the stools? The lack of tone is so marked that "postural" giddiness and semi-blackouts after any exertion, such as walking rapidly upstairs, are frequent. Heart and blood pressure fairly normal.

*A.—Adherent, viscous stools are described in intestinal putrefactive dyspepsia and in colitis. The physical basis of this adhesiveness is not known, but it is not due to mucus or fat in excess, for these make the stools slippery and easy to emulsify with water. The onset of putrefactive dyspepsia is probably due primarily to too rapid emptying of the stomach and small intestine, which may be related to the lack of "tone" elsewhere. A careful microscopic and chemical examination of the stools should be made, with special reference to bacterial flora, water content, hydrogen-ion concentration, excess of fat, and, if possible, organic acids and ammonia (Goiffon, R., *Manuel de Coprologie Clinique*, 3rd edition, 1935). If the diagnosis of putrefactive dyspepsia is confirmed by the presence of an alkaline stool with excess of ammonia and putrefactive organisms, the condition should be treated by a lacto-vegetarian diet. Carbohydrate fermentation should be promoted by the use of lactose or preferably uncooked rice starch, half a teaspoonful at meal times. A fractional test meal should also be performed and hydrochloric acid prescribed if achlorhydria is found. One of the vegetable mucilage aperients, such as psyllium seeds, of which there are several elegant proprietary preparations, would also be useful, particularly if the water content of the stool is subnormal.*

Achalasia in a Man of 60

Q.—I shall be grateful for advice on the treatment of a troublesome case of achalasia (cardiospasm) in an otherwise healthy man of sixty.

A.—The treatment of achalasia by drugs has been discussed in answer to a previous question (Aug. 7, p. 189). The simplest and most effective treatment of achalasia is undoubtedly Hurst's mercury bougie, which should be passed immediately before all meals for a fortnight and thereafter at gradually increasing intervals according to the degree of freedom from symptoms. If there is any oesophagitis, the diet should be fluid for the first fortnight. Half a pint of water should be drunk about 10 minutes after food to wash out the oesophagus, and this habit must be continued even after regular use of the bougie is no longer necessary. Operative treatment is not desirable except in the rare cases in which the oesophagus becomes elongated and kinked and the bougie cannot be passed. It may then be necessary to dilate the sphincter manually after opening the stomach.

Safety of Milk

Q.—Can a householder obtain reliable information as to the bacteriological safety of the milk he is compelled to purchase under the zoning order? What steps should he take to secure a test?

A.—If the milk is sold under the designation "Pasteurized" or "Tuberculin Tested (Pasteurized)," there is reasonable assurance that it will not contain pathogenic micro-organisms. If it is designated "Tuberculin Tested" or "Tuberculin Tested (Certified)," it is very likely to be free from tubercle bacilli. Otherwise it cannot be regarded as safe—and this applies whether the milk is sold as "Accredited" or as ordinary commercial milk. If the purchaser wishes to have a test done he must arrange for it privately at a laboratory which tests for fees, and the cost must be defrayed

by the purchaser himself, but the result of the examination of one sample is of little value for arriving at a conclusion as to the safety of milk. If he wishes to obtain from the vendor under the existing order one of the designated milks mentioned above, and if he cannot get satisfaction, he should make representations to the Divisional Food Officer for the area in which he resides, and he might also draw the attention of the local medical officer of health to the state of affairs. Apparently there is no firm obligation upon a vendor to obtain and supply such a milk when it is demanded. The whole position is very unsatisfactory, but it may be improved by the measures for compulsory pasteurization in large towns (except for certain milks sold under other designations) which the Government proposes to put before Parliament.

Pleuro-pericardial Rub

Q.—Seven months ago a soldier aged 25 reported sick with severe substernal pain of sudden onset, extending from the epigastrium to the root of the neck. It was aggravated by exertion. His pulse rate was 104, temperature 99° F. The outstanding feature was a very loud and typical pericardial friction sound, triple in character, and asynchronous with the heart sounds. I had little doubt that this patient had acute pericarditis, and the intensity of the pain necessitated morphine during the night. Next morning the pain was much improved, and the friction sound only just audible. On admission to hospital this physical sign had disappeared, and was never heard subsequently. An x-ray of the chest was normal. He returned to full duty in 10 days. He remained well until ten days ago, when he again reported sick with a similar precordial pain, and the same adventitious sound was heard. The pain and sound varied with posture, both disappearing in the semi-recumbent position: it was loudest when the patient lay flat. He was taken to hospital as quickly as possible, but again the friction sound disappeared on arrival. X-ray examination of the chest was again normal apart from "slight exaggeration of the lung markings in the right base." An E.C.G. was normal in all four leads. The sedimentation rate was 7 mm. in the first hour and 21 mm. in the second, with an average of 8.75 mm. The pain improved in a few days, and apart from slight dyspnoea and pain at the base of the neck on exertion, the patient again appears well. He says he has suffered neither from rheumatism nor from chest trouble.

I would be glad if any light could be thrown on the pathology of this condition, as I find it difficult to reconcile these transient attacks with the usually more serious implications of a pericardial rub. Could this man safely continue at work without further investigation or restriction?

A.—It may have been a severe local inflammation of the pleural fold in front of the pericardium, producing a pleuro-pericardial rub. Acute pericarditis seldom causes such severe pain—a contrast with pleuritis—and the normal electrocardiogram is much against involvement of the pericardium or the heart itself; so is the rapid and complete recovery. A pleuro-pericardial rub is not invariably influenced by respiration, though usually it is. Bodily movement would be expected to have some effect upon the pain. If pleuro-pericarditis is the explanation, the aetiology might not be related to any serious or known infection, but it would be well to limit physical activity for some weeks and to re-examine him monthly for a time.

Hyperemesis of Pregnancy and Rh Factor

Q.—Has the Rh factor any bearing on severe hyperemesis in a 3-para? The first child (female) was normal at birth, but there was jaundice and haemorrhage of the newborn in both the other children. The first of these (male) died, having been treated by injections of the mother's blood. The second (female) recovered, following treatment with vitamin K, 1 c.c.m., and father's blood, 10 c.c.m. Would vitamin K help the hyperemesis in the event of a fourth pregnancy? If not, what measures are advocated?

A.—Although toxæmia of pregnancy appears to be common in cases of the Rh incompatibility between mother and foetus, there is no evidence that hyperemesis is especially frequent in such cases. The history in this family is suggestive of Rh or similar incompatibility, since neonatal jaundice is characteristic and haemorrhagic manifestations are also rather frequent in babies suffering from icterus gravis. The Van den Bergh reaction is usually of direct positive type in icterus gravis, indicating that the icterus is not purely haemolytic but is associated with a degree of liver damage. This tends to lower the infant's prothrombin level below the normally low values of the neonatal period, and an increased tendency to haemorrhagic disease of the newborn might be expected. Recent work, however, indicates that the haemorrhagic tendency is sometimes the result of the haemolytic process itself, and in such cases vitamin K would not necessarily be effective.

In this family the blood of the parents should be tested for the Rh factor and that of the mother for any abnormal agglutinin; if the mother is found to be Rh-negative and the father Rh-positive, the recurrence of trouble in any future pregnancy should be anticipated, even in the absence of demonstrable anti-Rh agglutinins, and preparations should be made to treat the infant prophylactically by

the intravenous transfusion, immediately after birth, of Group O Rh-negative blood. The administration of vitamin K to the mother shortly before parturition would tend to correct the deficiency of prothrombin in the child's blood, but in Rh cases this is probably not the whole story, and transfusion is more likely to be effective in controlling the haemorrhagic tendency. For further details about such transfusions consult the M.R.C. pamphlet (see *Journal*, July 10, 1943).

There is nothing to indicate that vitamin K would be of value in the treatment of hyperemesis gravidarum, but it might be given purely empirically. Prophylactic treatment by a low-protein-and-fat diet rich in carbohydrates and with abundant fluids should be tried, but if hyperemesis occurs in a severe form the patient should be removed to hospital and glucose given intravenously.

Sensitivity to Sulphanilamide

Q.—Can you suggest a scheme of dosage to desensitize a patient who is allergic to sulphanilamide? He has been supplied with this tablet on several occasions on account of streptococcal tonsillitis but each time he has developed urticaria, and on one or two occasions angioneurotic oedema. The streptococcus itself does not appear to be the cause of the allergic response, since when purely local and symptomatic treatments are employed there is no urticarial reaction.

A.—It is practically impossible to desensitize patients who are drug-sensitive, getting asthma or urticaria on its ingestion, though some success can be achieved in cases of contact dermatitis due to chemical substances. In this case the following suggestions may be helpful: (a) Make sure the reaction is to the sulphanilamide and not to some aspirin taken at the same time, aspirin being the commonest drug causing sensitivity manifested by urticaria. (b) Use another drug with a similar action—e.g., penicillin when available. (c) Use other members of the series with as different a chemical make-up as possible, as the cause of the trouble is usually some special chemical radical. For example, people sensitive to quinine are usually only sensitive to the laevorotatory alkaloids, and hence can take quinidine. There seems to be a fair choice of sulphonamides at the moment to try.

Amphetamine in Narcolepsy

Q.—A man of 35, otherwise healthy, has been discharged from the Forces on account of narcolepsy. He has from one to four seizures daily, with an occasional clear day or week; they may be precipitated by emotion, but as a rule occur without apparent cause. They are completely controlled by amphetamine (benzedrine) sulphate, 30 mg. after breakfast and after lunch, with 10 or 20 mg. after tea. A reduction of this dose appears to be ineffective. Can this heavy dosage be maintained indefinitely with safety? How is amphetamine eliminated, and what are its deleterious effects? He has been informed that the dosage can be reduced by taking thyroid at the same time; is this so?

A.—The doses necessary in this case are rather high and their effects should be carefully watched, but larger doses have been given for at least 6 months without apparent serious harm. The obvious effects of overdosage are sleeplessness, excitement, tremors, and delirium. Loss of weight and anaemia are signs of danger. Aplastic anaemia has been recorded after the administration of 190 mg. in 19 days (*B.M.J.*, 1937, 2, 615). The drug is partly destroyed in the body, but about half of it appears in the urine in the course of a day or two after a single dose. The suggested effect of thyroid is doubtful.

Recurrent Erysipelas

Q.—A lady aged 55 has had four attacks of erysipelas during the past three years; the interval between the last two attacks was only six weeks. It begins in the same place each time—the left side of the face near the ear—and apparently spreads from the scalp. The attacks are mild and yield quickly to sulphonamides. Would a vaccine help, or can you offer any further suggestions regarding prophylaxis?

A.—There is apparently an individual predisposition to recurrence of erysipelas as there is to pneumonia and rheumatic fever. The recurrent attacks of pneumonia have been shown to be associated as a rule with different serological types of the pneumococcus; that is, the individual after an attack has acquired some resistance to that particular type of pneumococcus but is still more than ordinarily susceptible to other serological types of the organism. The same phenomenon may hold for erysipelas and the streptococcus, of which we now know there are many serological types. If that were so, a blunderbuss vaccine containing the more common infecting types of the haemolytic streptococcus might be worth trying as a prophylactic against further attacks of erysipelas. On the other hand, the recurrent attack may be due to the original infecting streptococcus, which has lain latent in the tissues until conditions are suitable for a recrudescence. In this connexion it is important that sulphonamide therapy be continued for 3 to 4 days after the

clinical infection has subsided. Erysipelas must often owe its origin to an abrasion of the skin, and patients after an attack might be advised to take particular care of the skin and avoid unnecessary exposure to extremes of heat and cold. Again, infection of the upper air passages is a frequent precursor of facial erysipelas, so that sinusitis, infected tonsils, and the like should be looked for and appropriately treated.

Psoriasis of Elbows and Knees

Q.—Can you suggest a complete cure for patches of psoriasis which have existed on both elbows and both knees for the past six years?

A.—There is no "complete"—i.e., permanent—cure for patches of psoriasis. The following methods will probably remove them for a longer or shorter period: (1) Rub in to the patches twice daily an ointment of 4% salicylic acid and 2% dithranol in vaseline, or preferably in an emulsifying base, and keep the same continually bandaged on, on lint or old linen. If necessary the strength of the dithranol may be increased to 4% when one is satisfied that the patient is not hypersensitive to the drug. The result of this treatment should be the reddening and brown staining of the treated skin, first round the patch and later on the patch itself. The treatment must be continued until all scales have come off and the site of the patch is just brown as the surrounding skin. This should take 2 to 3 weeks. The objections to dithranol are the risk of setting up dermatitis in a hypersensitive person, of conjunctivitis if any gets into the eyes, and of staining clothing and bed-linen. (2) If x-ray treatment is available, two to four doses of x rays, each of 100 r (unfiltered, 80 to 100 kV) at weekly intervals, localized to the patches and combined with the inunction twice daily of hydrarg. ammon. 2%, liq. picis carb. 12½%, in ung. paraffini B.P., will probably clear up the patches. This is a much cleaner method than the first.

A note on the treatment of psoriasis of the face and scalp appeared in the *Journal* of Oct. 9 (p. 472).

Menorrhagia and Hyperthyroidism

Q.—What is the treatment for a young unmarried woman of 23 years who suffers from apparently excessive monthly periods, menorrhagia? She is of the nervous type with symptoms of thyrotoxicosis, slightly enlarged thyroid, palpitation, dry mouth, and cold clammy sweats of hands. Rest helps her naturally during her periods, but does not diminish the monthly haemorrhage very much. Ergot makes her worse. What is the usual cause in such cases? The patient neither smokes nor drinks.

A.—Menorrhagia is not uncommon in thyrotoxicosis, and if local pelvic disease and blood disorders have been excluded in this case the menstrual disturbance should be regarded as another symptom of the thyroid dysfunction. Treatment of the menorrhagia, therefore, consists in treating its cause, the thyrotoxicosis. In the first place this should be by prolonged rest in bed with the regular administration of sedatives such as luminal, but, failing this, subtotal thyroidectomy may be required. Only if the menorrhagia persists after the thyrotoxicosis is cured should symptomatic treatment be considered.

Then calcium gluconate, crude liver extracts (containing "antihæmorrhagic factor"), and ascorbic acid, all given by mouth, regularly each day for 2 or 3 months, might be tried. Ethisterone, 5 mg. t.d.s. by mouth for 3 days pre-menstrually, is sometimes helpful. If there is no response to such simple empirical measures, endometrial biopsy should be carried out, and further treatment will depend on the endometrial picture.

Primary Amenorrhoea

Q.—A patient aged 20 years has primary amenorrhoea. The uterus and cervix are normal. Antuitrin "S" and thyroïd have been tried without result. As the patient is anxious to get married, what is the outlook?

A.—Amenorrhoea indicates that either the uterus, by reason of maldevelopment or disease, is incapable of responding to the normal hormone stimulus, or, if the uterus is normal, then the ovarian hormone stimulus is lacking or is being interfered with by some general disease such as tuberculosis. A diagnosis can be made only after further investigations such as x-ray of pituitary fossa, B.M.R. estimation, x-ray of chest, examination of blood, endometrial biopsy, and possibly a therapeutic test with oestrogen to see if the uterus responds. Amenorrhoea in itself is not harmful to general health nor would it necessarily interfere with marital life. The prospects for pregnancy, however, are bad, though, again, pregnancy is possible even in the presence of amenorrhoea; it depends on the cause of the latter.

Parodontal Disease

Q.—May I have suggestions for a radical cure for "bleeding gums" and gingivitis? I have tried many methods without success.

A.—Bleeding gums are a symptom of parodontal disease (pyorrhoea alveolaris), which is notoriously difficult to treat. Little can be expected from general measures. Vaccines and vitamins B and

C have their advocates, but the results are usually disappointing. Mouth breathing is an important aetiological factor and should be corrected. Local treatment is of more value than general treatment. It consists in the removal of scale, reduction and cleansing of pockets and interdental spaces, the surgical deletion of pocket and massage of the gum. If x-ray examination shows much osteoporosis or if there are clinical effects from septic absorption, it is probably wiser to proceed to extraction of the teeth right away.

Tobacco and Fehling's Test

Q.—The urine of a woman patient reduced Fehling's solution to a bottle-green colour, with a slight yellow precipitate. The green seemed to me to be the wrong shade for sugar, and as the patient is a fairly heavy smoker I wondered if there might be a link. I did a very crude test with tobacco taken from the end of a cigar and Fehling's, and got the exact shade of green that I did with patient's urine test. The tobacco further reduced the Fehling's yellow. Is there any real significance in this?

A.—The reduction obtained with crude extract of tobacco is due to the presence of glucose, which occurs in Virginian dried American tobacco to the extent of 6.9%. The appearance of the cuprous oxide which is obtained by the action of glucose on Fehling's or Benedict's reagents is dependent on the presence of other substances in solution. For example, glucose alone gives a brown finely divided precipitate, whereas in the presence of creatinine the precipitate is yellowish-orange and very bulky. As a result, a small quantity of glucose in a concentrated urine may give a bottle-green colour, with a slight yellow precipitate, similar to the reduction described. It would be interesting to carry out a fermentation test on the urine. If the reducing substance is removed by the action of yeast, it is most probably glucose.

LETTERS, NOTES, ETC.

Treatment of Schizophrenia

Dr. HORACE HILL (Salisbury) writes: In addition to the treatment described (*Journal*, Aug. 7, p. 159) I would suggest one or two courses of the combined histamine and insulin treatment, which gives very good results.

Strychnine for Paralysis

Dr. J. C. JONES (London, S.E.25) writes: It does not seem to be commonly realized that ascending doses of strychnine are extraordinarily effective in treating the paralysis of infantile paralysis and also diphtheritic paralysis. The dose of liq. strych. is increased by 1 minim per day until saturation is attained. When will someone fortunately placed person collect a series of cases treated in this way? I have never sent a case of infantile paralysis to hospital and I have never failed to get 100% recovery within a few weeks.

Medicine 100 Years Ago

Flight Lieut. KEITH F. D. SWEETMAN, Royal Australian Air Force writes from Queensland: It is with regret that I have noticed the last four or five copies of the *Journal* (last copy received dated April 15, 1943) the disappearance of that very interesting weekly feature, "Medicine 100 Years Ago," which always provided a pleasant five minutes' reading. As quoted in your review on the book *War Surgery* by Dr. J. Trueta, Osler reminded us of the historical method of approach is an absolute necessity in the solution of most of the problems in medicine, so I feel that the disappearance of the above-mentioned series is to be regretted. Also I am certain that there are many other medical men, removed from the places where the medical history of our country was, and is, being made, who are regretting your omission. I make a plea for the resumption of this weekly feature and its expansion into a full column, giving not only one extract from past literature, but all the available data as to the medical happenings during that week a hundred years ago, both in Great Britain and in any other country where medical progress was made.

Correction

Drs. JAMES P. A. HALCROW and N. O. RODGER write: May be permitted space to correct an error in our article on infectious mononucleosis (*Oct. 9*, p. 443). The reference to Downey Stasney should read *Folia Haemat. Lpz.*, 1936, 54, 417, not vol. We are indebted to Dr. A. Piney for pointing out this mistake.

Disclaimer

Major JOHN W. WISHART, R.A.M.C., writes from a General Hospital: It has been brought to my notice from several sources that an article appeared in the lay press recently in which my name was mentioned in connexion with the treatment of neuroses in North Africa. I have not seen this article and have no knowledge of the source from which it originated. Any article which may have appeared was published without my knowledge or consent.

LONDON SATURDAY OCTOBER 30 1943

TRANSPLANTATION OF THE URETERS INTO THE LARGE BOWEL*

by

G. GREY TURNER, LL.D., MS., F.R.C.S.

Professor of Surgery, University of London; Director of the Surgical Unit, British Postgraduate Medical School

This subject has always interested me, for at the outset of my surgical career I saw cases of ectopia which made me realize the utter misery of the sufferers, so often to become unwanted outcasts who, like Job, survived to "curse the day wherein they were born." Treatment was most unsatisfactory, and though transplantation of the ureters into the bowel seemed the best solution I was brought up in the belief that the operation was extremely dangerous and sure to be followed by ascending renal infection and rapid death: the only justification for a return to the subject is because some members of the profession still appear to be obsessed by this fear.

For me the bright lamp of surgical progress in this field was lighted in 1911 when Stiles of Edinburgh read a paper in Denver City on two cases in which he had successfully transplanted the ureters by burying them obliquely in the wall of the bowel, in much the same way that the catheter is buried in the stomach wall in the Witzel method of gastrostomy.

After-results

In 1927 I delivered a Hunterian Lecture on this subject, and was able to give the after-history of 17 personal cases from a few months to 15 years after transplantation (Turner, 1929). The subsequent history of these same patients after the lapse of a

After-history of 9 Cases of Transplantation for Congenital Defects with Incontinence All Previously Reported (Turner, 1929)

Case No.	Sex	Age at Operation (years)	No. in D.J.S. Vol. 17	Time since Operation (years)	Present Condition	Further Particulars
1	Male	8	1	30	In good health	Working long hours at munitions
2	Female	22	2	29	"	Three children born since operation. Does all own household duties. Twice had stone removed from right kidney and ureter
3	Male	19	3	25	"	Has worked as a farm labourer. Married
4	Female	6	5	25	"	Stone removed from kidney. Married: no children
5	Male	5	7	23	"	During one recent year several attacks of renal pain. Married
6	Male	10	12	19	"	Trouble with inguinal hernia. Otherwise well. Does heavy work
7	Male	8½	15	17	"	Nephrectomy for pyonephrosis—persistent urinary fistula. Does heavy work down a mine
8	Male	3	16	16	"	
9	Female	3½	17	16	"	Has always been splendidly well

further 16 years is now presented (see Table). The numbers of the cases recorded in the original paper are placed in the fourth column. The patients have been very closely watched, and those who have been admitted to hospital for various reasons have

been submitted to detailed examination. In no case has there been gross evidence of renal deterioration. In 1936 J. H. Saint examined several of these patients by the method of intravenous pyelography, and the results were published in a joint paper (Turner and Saint, 1936). In the original 17 cases there were four deaths directly due to the operation (peritonitis 3, septic dermatitis 1). Three patients subsequently died—from intestinal obstruction, sepsis following a plastic operation after removal of the ectopic bladder, and haemorrhage after plastic repair of the penis respectively. Thus none of the patients who recovered have subsequently died because their ureters were transplanted. Of the 9 surviving cases the essential details are set out in the accompanying table.

In Case 7 an enormously dilated ureter could not be buried and was simply tucked into the bowel end to the side. In Case 9 a submucous bed was prepared. In the other cases the original method of Stiles was used, one ureter being implanted at a time and with a varying interval between interventions. Full details of the operations are given in the original paper. "In good health" means that the patients can stand up to their environment and take their place among their fellows. No. 1 has never been a big strong person, but he has developed quite well, played games, including football, and has always been ready for work when it was available. No. 2 is a brave woman now 51 years of age. Her first child was born three years after the operation, and both pregnancy and delivery were without unusual incident. Ever since the operation she has had some pain in the back, but it has only been very troublesome at infrequent intervals during the last five years. In 1938 a phosphatic calculus was removed from the right kidney, which was considerably dilated, and early this year a large calculus was removed from the corresponding ureter. The patient is now very well. Except for these attacks her health has been good, and her greatest happiness has been to look after her family and household. She has carried out all the domestic duties which fall to the lot of a North Country woman of the artisan class. After her day's work she has often visited the pictures and has gone from home on holiday each year. For years No. 3 did the hard work of a general farm labourer. His marriage about three years ago was for companionship, but is not entirely Platonic. Case 4 has also had a stone removed from the right kidney 14 years after the transplantation; but she has always been well and active, carrying on the work of a ladies' maid, which in her case entailed a considerable amount of travelling. Three years ago she married, and is anxiously awaiting maternity. No. 5 was a feeble child but has developed into a sturdy young fellow. Four years ago he was exceptionally well, was working long hours, and dancing in the evenings by way of relaxation. During the past twelve months he has had several attacks of renal pain; but these symptoms left him after passage of a considerable amount of grit, and he is now working regularly in charge of a factory. No. 6 has enjoyed good health except for troubles due to double inguinal herniae, one of which had to be operated upon in a state of strangulation; but despite this handicap he puts in a long day as a crane-man. No. 7 has had a tedious time with many vicissitudes, including nephrectomy for pyonephrosis. None the less he is well developed, strong and active, and capable of hard work. No. 8 has been difficult to keep in touch with, but he is reported to be well and strong. No. 9 was operated upon at an early age, but she made an easy recovery, has developed normally, has never shown any untoward symptoms, and has grown into an attractive girl who enjoys excellent health. Many other cases operated upon since the above series have been equally satisfactory, and I would just recall a charming girl born with an ectopic bladder whose parents were thrown into the depths of despair as the result of the utterly pessimistic outlook of the

* Presidential address delivered at the Medical Society of London, Oct. 18, 1943, much abridged.

consulting surgeon who was called to see the case a few days after birth. The transplantations were carried out between 3 and 4, and now, eight years later, the child is perfectly well, highly intelligent, and especially fond of swimming. Also another girl, who wrote four years after operation: "I have to catch a bus in the mornings at a quarter to eight in the black-out, but it is fun!" An officer whose ureters were transplanted just previous to total cystectomy for neoplasm is now, two years later, back to his military duties, albeit on the home front, while in like case a street trader is actively employed in his traffic. I used to feel that every case of transplantation would sooner or later show some evidence of ascending infection, but I am now hopeful that with the great simplification of the technique there may be many in which it never occurs. The exact condition of these patients may be regarded as the results of an experiment in applied physiology, and can be detailed as follows.

Details of Results

Effect on the Economy of the Body.—Just after the transplantation the patients are invariably abnormally thirsty, and this may continue for about a year. During this period they often lose weight, and sometimes very considerably. After this time thirst diminishes and they not only regain lost weight but begin to put on flesh, so that they come to look plump and well nourished. Appetite is usually good and mental acuity more than average. They behave like normal individuals, are cheerful and happy, and able to work and play like others of their station. They can also stand up to the buffets of their environment, including physiological processes like pregnancy, operations, and illness.

Rectal Function and Control.—In nearly all my cases this has been satisfactory, though in two of them continence during the night has never been acquired, though these same patients have complete control by day. While there is some variation, most patients can hold the contents of the rectum for three to four hours at a stretch, and the call is not so urgent but what they can await a convenient opportunity with confidence. Some patients sleep throughout the night without being disturbed, while others may rise once or twice. All agree that the behaviour of the rectum is much influenced by the general health. With exhaustion or indisposition rectal calls are more frequent. The contents voided are usually an intimate mixture of faeces and urine, but sometimes the same patient may pass clear or opalescent urine at one time and a solid evacuation at another. The rectal mucous membrane is unaffected and, except for unusual moisture, looks normal when inspected through the sigmoidoscope.

Where the Urine is Stored.—At the time of my first communication many considerations led me to conclude that the urine was stored in the large bowel and not in the rectum. This conclusion is amply supported by urography.

Effect on the Kidneys and Ureters.—The changes in structure are sometimes very striking. In the first few weeks the ureters and pelvis may be dilated, and this dilatation may persist and increase. In the series of examinations made in collaboration with J. H. Saint four out of six patients showed a moderate degree of unilateral hydronephrosis, and in another the condition was bilateral. The most striking feature was the general good health of the patients examined. Marked unilateral hydronephrosis was also found in a patient who died subsequent to operation for intestinal obstruction, but that boy had enjoyed good health until it was fatal illness. In nearly all of the earlier cases there was clinical evidence of some ascending renal infection, but for the most part it was transient and did not materially interfere with recovery. From the clinical aspect only those cases in which there has been obstruction in the lower ureter have suffered seriously. This is in keeping with general pathology, and conforms to the rule that infection with good drainage is often neither very troublesome or dangerous. The ureter may be dilated or may look normal, but at the actual junction with the bowel and the opening into the lumen is not always demonstrable either by radiographs or by sigmoidoscopic examination. When visible it may take the form of a nipple with a terminal or lateral orifice, a rosette, or a tiny opening hidden behind one of the rectal folds.

Should Both Ureters be Transplanted at the Same Sitting?

Up till quite recently I have always taken the view that it is safer to transplant one ureter at a time, and the wisdom of this course has been borne out by statistics. With better understanding of the problems involved, a simpler technique, and more knowledge of after-care, I am tending more and more to carry out

a simultaneous transplantation, except in children, and even in them the hazards of a second anaesthetic may perhaps balance the only slight extra risk of the double transplantation.

What is the Best Technique?

The technique has now been very much simplified, and is carried out without any special apparatus. Clamps are not used either for the ureter or for the colon. Coffey's tubes are no longer employed, and Charles Mayo's catgut guide has been discarded. The main points are to make an oblique implantation into a submucous bed in the bowel without kinking or compression and with due regard for the blood supply of the ureter. Compression from too tight suturing or the result of haematoma or traumatic oedema is probably the most harmful thing that can occur. Fine 3/0 or 6/0 chromic catgut is used throughout. Drainage is not employed.

Preparation and Operation

Preparation will differ a little, depending on whether the surgeon is dealing with a congenital defect in an otherwise healthy child or the operation is for the relief of some condition, such as malignant disease of the bladder, likely to be associated with sepsis or general deterioration. No operation should be done until the renal function has been raised to as nearly the normal standard as possible. The bowel should be well cleared by a reliable purgative or by an enema not later than 12 hours before operation. If there is distension or constipation a full dose of castor oil is the best preparation. No attempt should be made to sterilize the bowel or even to cleanse it by repeated irrigation, which may result in the surgeon's encountering a wet puddle in the pelvic colon. The choice of anaesthetic will depend partly on the condition of the patient and partly on the practice of the surgeon, but whatever method is employed complete relaxation is necessary. The patient is placed in the Trendelenburg position and the abdomen opened by one of the vertical incisions, which must be long enough to give ready access to the pelvis. I have made it a practice to transplant the right ureter first, but I am not able to give any valid reason for the choice. If both are to be transplanted, at the same sitting I am sure that it should be into the same side of the bowel, and the right or inner side is the more convenient. To bring this about it is usually best to pick up the left ureter on the outer side of the sigmoid and to bring it through the mesocolon to the inner side, where it is made to enter the bowel about 1½ in. higher than its fellow. It is usually easy to identify the ureter as it crosses the pelvic brim. Spontaneous vermiculation, or this movement elicited by mechanical stimulation, is characteristic. The posterior peritoneum is incised in the length of the ureter for about 3 in., and the ureter is gently lifted from its bed and traced towards the bladder. Not more than 2½ to 3 in. should be isolated: in this respect illustrations in surgical journals are misleading. At the lower end the ureter is clamped and divided obliquely; the end is securely tied, and its open end carbolized and allowed to retract. The upper end is held by a suture passed from its lumen and out through its upper surface a quarter of an inch from the cut end. This is tied, and is subsequently used for drawing the ureter into the lumen of the bowel and for fixing it to the bowel wall. The ureter is now turned backwards over a pad of gauze; this kinking is enough to prevent the escape of urine. A few interrupted sutures draw together the edges of the incision in the posterior parietal peritoneum.

The position of the incision to be made in the bowel is now determined by finding out where the ureter lies most comfortably against it without kinking. The aim is to carry the ureter obliquely into the bowel in the same alignment as it occupies in its retro-peritoneal bed. The site for the right ureter will probably be in the lowest part of the sigmoid or the uppermost end of the first part of the rectum. The actual incision in the bowel will usually be 1½ or 2 in. long, and this is marked out by guide sutures. The incision is made obliquely through the muscular wall down to the submucous layer. The edges will retract, but this process may require to be helped by gently spreading with dissecting forceps or a few touches of the knife, used with the blade on the flat. At the lower end of this oblique bed a small hole is made into the bowel lumen. The idea is to make such an aperture as will comfortably admit the ureter, but in practice it usually works out a good deal larger. Both ends of the stitch on the ureter are now threaded on a small round needle, which is passed through the hole into the bowel and out through the whole

thickness of its wall half an inch beyond the aperture. The ureter may have to be manipulated through the latter. Both are pulled upon to draw the ureter to this site and well up against the inner surface of the bowel. The ends are then tied firmly, but not so tightly as to cut through the tissues. The edges of the incision in the muscular layer are now sewn over the ureter with four or five interrupted sutures. If there has been any doubt about the fixation of the ureter the first muscular stitch takes a bite of its wall. The peritoneum is then drawn together over the first sutures, taking great care to bury the ureter-fixation stitch properly. One or two more than the number of deep stitches will be required. It is particularly important that the stitch nearest to where the ureter enters the bowel should be lax, as it is at this point that obstruction may be caused by subsequent oedema or kinking. If after tying this last stitch the ureter is seen to fill up, the suture is causing obstruction and must be removed. If excretion is going on, the urine should be escaping into the bowel while the anastomosis is being made, and the ureter should never distend. The ends of this last stitch are left long, and are used to anchor the bowel to the cut edge of the posterior parietal peritoneum. In this way at the conclusion of the operation the ureter passes directly from its retroperitoneal bed into the bowel, so that it has no intraperitoneal course. If the second ureter is to be transplanted at once the same steps are taken, but the incision in the bowel wall should be an inch or an inch and a half higher up than the first implantation. After completing the toilet of the peritoneum the omentum should be crowded into the pelvis and the patient brought to the horizontal position for closure of the abdomen. For some three years now I have omitted drainage from the site, but it is a perfectly rational safeguard, and the surgeon need not hesitate to use it. The abdominal wall must be very carefully closed, some through-and-through sutures being used. As a last step a tube about forefinger size is passed into the ampulla of the rectum and fixed to the anal margin by suture. This is to prevent the accumulation of a puddle in the rectum which might encourage infection.

The whole procedure takes from three-quarters of an hour to an hour and a quarter, depending upon whether or not both ureters are transplanted.

Immediate After-progress and Treatment

There should be no shock and very little upset of any sort. Urine may be discharged into the rectum from the outset, but it is more usual for uremia to be delayed for about six hours. At all events, only if there is no evidence of secretion by the end of that time should active steps be taken to encourage it. Some patients vomit a good deal and a moderate amount of distension is not uncommon. Such symptoms nearly always clear up as soon as uremia is freely established. I have always avoided the use of enemata, fearing to disturb the site of anastomosis. The patient reaches the ward with a glucose-saline drip *in situ*, and this is continued until there is a free discharge of urine from the rectal tube. When the patient recovers from the anaesthetic, the drinking of hot water is allowed and, in the absence of vomiting or distension, encouraged. It is only in cases with rather poor renal output or in which uremia is delayed that the intravenous sodium sulphate 4.3% is employed.* The rectal tube should be removed in four days, or earlier if it is much resented. Thereafter there may be incontinence for some days, especially in children, and adults may have very frequent calls—perhaps every hour. But even children acquire rectal control quite quickly, and nearly always by the time they are ready to leave hospital—in three or four weeks. Of course some education is usually necessary, and to this end it may be a help to keep the bed-pan in the bed. A capable and understanding nurse will usually manage to assist even small children to acquire control within this time.

Complications

In the early stage anuria, chest troubles, and peritonitis are the only likely troubles. At the end of about a week distension, local tenderness in either iliac fossa, quickening pulse, elevated temperature, and general malaise are very suggestive of intra- or extra-peritoneal infections about the site of anastomosis. Such a condition is grave but not necessarily fatal. In two cases (Nos. 4 and 5) a localized abscess formed and after evacuation

was followed by urinary fistula, yet spontaneous recovery ultimately ensued, and both patients are now, many years afterwards, alive and well. Some infection of the kidney used to be so frequent as to be looked upon as part of the normal convalescence, but in more recent years it has seldom occurred, possibly owing to the simplification of the technique. Most cases turn out to be mild, but, even so, the onset may be rather alarming and attended with considerable general disturbance. As a rule this soon settles down, leaving a swollen tender kidney with some fever as the only indication. In the more serious types things go from bad to worse until the patient presents the picture of acute ascending pyelonephritis, but I have not seen death from this cause for some years. In his anxiety and apprehension about possible renal infections the surgeon must not forget that these patients are liable to the occasional complications attending on laparotomy for any purpose. I have successfully dealt with a case (No. 3) in which a loop of small intestine escaped through the wound and became strangulated, and the burst wound is not unknown.

Mortality

The mortality rate depends to a considerable extent on the condition demanding the operation. In the non-malignant cases and especially the congenital deformities it should be very low—perhaps 5%—but in the malignant cases such a low rate is not to be expected if the possible advantages of the operation are to be offered to the greatest number of sufferers. In children some deaths have been due to chest complications and to the exanthemata, and I would stress the wisdom of choosing the summer months for the ordeal and of keeping children in hospital for a fortnight before operation.

When to Transplant the Second Ureter

There is no stated time for dealing with the second ureter, and the interval must depend on the progress made after the first intervention. If all goes perfectly well, three weeks has proved a proper interval; should it be otherwise, the surgeon must bide his time. The only error is to re-operate too soon.

Some Late Sequelae

If pyelitis is going to develop it usually comes on within a fortnight of the transplantation, but once having developed it tends to recur at varying intervals, perhaps over a lifetime. Hydro-nephrosis, on the other hand, probably develops over the course of months, and may not give rise to symptoms unless it becomes infected. Quite often it is discovered only because looked for. Calculus formation is not very rare, for it occurred three times among my first 13 patients who lived long enough to develop the condition. The symptoms became suggestive 15 years, 22 years, and 25 years after the original operation. Frequency of rectal micturition has seldom been a constant feature, but it may be an accompaniment of general ill-health. Rectal incontinence for urine is in my experience the most disturbing sequel. Fortunately it is unusual. In spite of painstaking investigation I have been unable to discover the cause, nor have I been successful in treatment. Wearing a rectal tube at night—a large catheter of the de Pezzer type—is a useful palliative measure.

Special Groups of Cases.

Congenital Anomalies.—Of these the commonest is ectopia vesicae, which is said to occur once in every 50,000 births. The next are the lesser degrees of the same condition, such as complete epispadias in the male and the corresponding anomaly in the female known as subsymphysial epispadias. The age at which to operate is an important problem. I consider that the optimum time will occur somewhere between 4 and 6. But it is not so much a question of the number of years but of the condition, and whatever the age the operation must not be carried out until the child is in established good health. Many a child at 4 is better fitted for the operation than others at 6. But it is never too late to consider operation if congenital deformity is the indication, and my friend Mr. Norman Hodgson dealt most successfully with a case of ectopia in a man of 51 who, by a strange irony, had consulted me 30 years previously, only to be told that no operation was feasible. As a rule children do better than adults, and it is surprising how readily they accommodate themselves to the altered physiological condition.

* 42.85 g. of hydrated sodium sulphate (Glauber's salt) dissolved in one litre of distilled water gives an isotonic solution of 4.3%.

The exposed mucous membrane of the ectopic bladder is a distinct danger, and many examples of the development of epithelioma have been recorded. Quite apart from this risk it is offensive to the eye, may give rise to an unpleasant discharge, and is liable to mild injury and excoriation. In either sex some sort of plastic repair of the affected area is desirable.

With the lesser anomalies the question of marriage is often raised, and even in complete ectopia patients of either sex have sought the consolation of matrimony. The female with a normal partner may prove fruitful, and there is no reason why such marriages should not be happy. There appears to be no special risk in pregnancy, and, since the pubes is constantly separated, labour is often easy (Case 2). In the male sexual gratification is said to occur, but neither of my married male patients has as yet become a father. Now that the transplantation is less likely to be attended by sequelae, I welcome the opportunity of carrying out more careful and complete restoration of the genitalia.

Separation of the Pubic Bones.—In the case of complete ectopia the pubic symphysis is separated to the extent of from four to six inches, but the bones are connected by a very strong ligament. It is often assumed that such a degree of separation will result in marked disability, but though the thighs are more or less widely separated and the patient walks with a characteristic gait, they are usually quite strong and able to carry out ordinary activities without impediment.

Other Pre-operative Problems that may Arise.—Sometimes there is weakness of the anus with incontinence, and on occasions prolapse. If this is associated with some degree of spina bifida and perhaps weakness of the lower limbs no improvement can be expected, and transplantation into the usual site is contraindicated. Confronted with these circumstances Hey Groves made the transplantation into the caecum, and combined this with a left inguinal colotomy. As a result not too frequent pulaccous stools could be easily controlled by a colotomy belt, and for some years the patient was able to lead a sheltered but useful life.

Contraindications to Transplantation.—Marked pyelitis and hydronephrosis are usually regarded as contraindications to transplantation. It is always worth while establishing external loin drainage by nephrostomy and, if sufficient improvement follows, to proceed to transplantation while the drainage is still operating.

The Widening Scope for Transplantation

For many cases of malignant disease of the bladder total cystectomy holds out the best prospect of long palliation or even cure. In this operation it is necessary to divert the urine, and by far the best plan is to carry the ureters into the bowel. The technique is the same as that used in other cases. When the transplantation is a proved success—and this is usually assured three or four weeks—the removal of the bladder may be carried out.

In some cases of malignant disease of the cervix extension to the adjoining bladder renders treatment both by radium and by hysterectomy impracticable. In such cases total hysterectomy, together with simultaneous removal of the bladder, holds out some prospect, and in the absence of glandular involvement or distant dissemination should be practised. The transplantation of the ureters should be a first stage, and the next part of the operation should not be undertaken until the patient has become acclimatized under the new physiological conditions. An interval of 6 to 8 weeks will probably suffice, but there should be no unwarranted haste.

For some years now the operation has been used for certain intractable cases of vesico-vaginal fistula. In such cases transplantation should not be combined with a last desperate attempt at local repair, but should be a deliberate intervention only to be carried out after proper preparation. In the systolic bladder, which is sometimes a problem after the successful removal of tuberculous kidney, diversion of the ureter into the bowel may bring great relief.

Transplantation has also been used in certain cases of severe injury to the urethra usually associated with fractured pelvis. Though this indication is among the rarest, it should be kept in mind.

OCULAR MANIFESTATIONS OF NEUROSES COMMONLY FOUND AMONG SOLDIERS

BY

I. C. MICHAELSON, F.R.F.P.S.

Major, R.A.M.C.; Ophthalmic Specialist, British General Hospital
Extra Surgeon, Glasgow Eye Infirmary

Fear and environmental stress are very prevalent in wartime and often give rise to chronic anxiety. Many soldiers react to such a chronic anxiety by developing a neurosis, of which there are two main varieties—hysteria and the chronic anxiety state. Whether one or the other will develop depends on the individual personality type.

The hysteric has an essentially childish personality with an undeveloped or perhaps only unsustained sense of social responsibility. He reacts to the anxiety by dissociation, which may affect nerve, muscle, bone, joint, an entire limb, memory, the conscious state, etc. He is very open to suggestion, and the type of somatic localization may be suggested by his observation of the infirmities of others or his memory of past disabilities within himself. In this way undue prominence is given to a condition already present, or else one is created entirely *ab initio*. The somatic incapacity is such as to still the anxiety or the conflict that may have arisen between it and duty. The more successfully this is done the happier is the patient, who may indeed wear a fixed look of quiet satisfaction throughout the day.

The patient who develops a chronic anxiety state is usually a more mature personality with some awareness of his obligation to society. His reaction to the anxiety provoked by fear or environmental stress is different from that of the hysteric. The early somatic upset appears to take place in the endocrinal and autonomic systems, leading to disturbances of the vasomotor, respiratory, sudomotor, or gastro-intestinal system. In this way are produced palpitations, vascular throbbing, headache, syncope, flushes, paraesthesia, breathlessness, sighing, undue sweatings, vomiting, diarrhoea, and dry mouth. The somatic incapacity is frequently not sufficient to assuage the anxiety of the patient, who may present a worried, unconfident attitude to the outside world.

As a result of hysteria and chronic anxiety state, various conditions arise in and around the eye. Indeed, it may be said without exaggeration that half of the soldiers presenting themselves at the out-patients' room of the eye department of this hospital in the Middle East have complaints which may fairly be described as functional. The most frequent, and those that will be dealt with in this report, are defective day vision, defective night vision, asthenopia, diplopia, headaches, photophobia, spots before eyes, and epiphora. All of these symptoms are found in organic conditions. Investigations into each of them should therefore take three main directions: (1) exclusion of organic disease, or, if present, an assessment of its role in the production of the symptoms (organ-symptom parallelism); (2) a detailed investigation into the nature of the symptoms; (3) some investigation into the patient's personality (while in difficult cases this is the sphere of the whole-time psychiatrist, the ophthalmologist should be capable of the simpler approaches). As investigation No. 3 applies to all the symptoms similarly, a brief generalization will be made now of the main points of inquiry.

Inquiry should be made into the presence of any worries, dislikes, or fears, and the degree of duty sense as evidenced by his former reactions to life. Search should be made for anything in the personal or family experiences of the patient, or in his general environment, that might have suggested the symptom to him. This may be a weakness of one eye which the patient had many years ago, or a history of blindness in his family, or the defective night vision of which his friend in the unit has complained. The relation of the symptom to change of environment should be noted, especially when a new climate provides factors, such as heat and glare, which can be blamed for it. It is noticeable how often among the troops in the Middle East a visual complaint began on the voyage out between Freetown and Capetown. It is as if there were an incubation period for the symptom.

The reaction of the patient during the examination should be carefully noted. Is he "too accepting" of the symptom, or is he disgruntled or even aggressive? Are his responses variable, and is he open to suggestion? Is there hesitancy of speech, or is there a stutter? Note if his attention wanders during the course of the examination.

After such inquiry a general idea of the personality pattern of the patient should be known.

Defective Day Vision

Defective vision is a common functional symptom. It may vary from complete blindness of one or both eyes to a lowering of visual acuity to the neighbourhood of 6/24 or 6/36.

It should not be difficult to diagnose the presence of organic disease or disability. In disseminated sclerosis, however, this may not be very easy. The main difficulty is to be able to state that a given organic condition is sufficient to account for the degree of the symptom. Only experience can tell the ophthalmologist how much visual defect can be expected from an organic condition—in other words, whether or not an "organ-symptom parallelism" is present in any particular patient. This difficulty is encountered particularly in fairly high astigmatism. It is often not possible to state definitely that a patient whose 3 dioptres astigmatism has been corrected with a lens should see more than the admitted 6/24. If the condition is bilateral the question of amblyopia does not arise in such cases.

A detailed investigation into the nature of the symptom should now be made. Most symptoms can be analysed and the component parts found to have a certain parallelism with each other. With vision, investigation into this "symptom parallelism" can be carried out in different ways.

The two main methods used in this department are tests of visual fields and the plotting of vision correlation curves. The visual field tests are well known, and are dependent on the fact that the fields for white targets of different sizes have a certain relation to each other and to fields for targets of different colours. In functional conditions the normal relation is upset. For example, the field for a 5-mm. white target may be larger than that for a 10-mm. target in certain meridians. A correlation curve depends on the simple fact that the number of lines read on a Snellen chart varies fairly directly with the distance of the patient from the chart. The acuity is taken at six to eight different distances from the chart, starting at the furthest one. It is important to vary the order in which the acuity at different distances is taken. A graph is then made, using the distances from chart as abscissae and the Snellen lines read as ordinates. In normal cases the resulting graph is almost a straight line. Fig. 1 is an example of such.

FIG. 1.—Correlation visual curve of a case of refraction error. (Note that the line is almost straight except at the end.)

In functional visual defect the graph is not straight. Fig. 2 shows graphs taken from a soldier with hysterical amblyopia of both eyes.

Important points to elucidate in the psychiatric approaches to such cases are the presence in the patient's history of any eye condition that may have made him "vision-subconscious" and his suggestibility to further acuity of vision during the test.

Pentothal sodium is an excellent diagnostic adjunct in cases in which the amblyopia is complete in one or both eyes.

It is the experience in this department that hysterical defects cannot with certainty be differentiated from simulation or malingering by physical tests only. In these tests it is not possible to exclude with confidence the effect of suggestion. The ultimate differential diagnosis between hysteria and simulation or malingering must be based on the psychiatric assessment.

FIG. 2.—Correlation visual curves of a case of hysterical amblyopia of both eyes. (Note variation in direction of curves.)

Treatment of Defective Day Vision

As most of these cases are hysterical the treatment is difficult. The visual defect may be removed by suggestion with or without the use of narco-analysis, but the underlying personality defect persists and may show itself later as a relapse of the visual defect or as a somatic disturbance elsewhere. Patients who have had complete blindness in one or both eyes before treatment are unlikely, in our experience, to become fit to return to a forward area. They may, however, carry out useful duties at the base for a long time. Indeed, a relapse may never occur if the precipitating factor of the emotional disturbance has been removed. Patients who have a partial loss of vision—to, say, 6/24—do not seem to do well, and often require to be invalidated. It is important to have the help of a trained psychiatrist in the diagnosis, and especially in the disposal of cases of severe hysteria. In the exigencies of war, however, it is rarely possible for him to effect the profound personality change necessary for the permanent removal of the underlying cause of the patient's symptoms.

Defective Night Vision

Defective vision in the dark is a common complaint among troops. Most of these patients state that in the dark it was necessary for them to take a companion's arm. This is a convenient mode of assessing the symptom, as it supplies a certain relative quality to the patient's complaint. Many state that they had bumped into objects in the dark or fallen into slit-trenches. Of this it must be said at once that there are few people who have not had similar experiences since the institution of the black-out.

Defective night vision may be a symptom of organic disease. It may be found in moderate as well as high degrees of myopia, in choroiditis, retinitis pigmentosa, vitamin A deficiency, and toxæmia. Every patient complaining of this symptom should be examined for these conditions. During the past six months three cases of retinitis pigmentosa were seen in this hospital. It must be borne in mind that defective night vision may precede the appearance of the pigment in the retina. During the past year we have seen only one case in which food deficiency was a possible cause. There was one case of alcoholism, and it is suggested that inquiries into this condition should be made in every instance.

Measurements of vision in the dark are made on a dark adaptometer. For this purpose Koch's modification of the Hecht apparatus is used. With it a sufficiently accurate measurement of the minimum light and form senses can be obtained. The light minimum can be measured from 2 to 6 micro-milliamperes (log units— μ ml.). The minimum form sense is measured by the amount of light necessary to determine the

letter "E" 10 mm. in size and placed 380 mm. from the eyes. As the "E" can be revolved a check on the patient's accuracy can be made. The minimum light sense is usually examined after 3 and after 30 minutes' dark adaptation. The minimum form sense is examined after 30 minutes' dark adaptation. The following are normal figures on this instrument:

Minimum light sense: 5.2 μ ml. after 3 minutes

3 μ ml. after 30 minutes

Minimum form sense: "E" recognized by 30% with 4.2-5.5 μ ml.

In pathological conditions there is usually a fairly parallel diminution in minimum light and form senses. In functional conditions there may be a gross disturbance in this "symptom parallelism." For example, in repeated cases of neurosis with complaints of defective night vision the minimum light sense after 30 minutes' dark adaptation was in the proximity of 3 μ ml., yet the "E" was not perceived at this point even with 6 μ ml. This lack of "symptom parallelism" is similar to that already described above, and in some cases may be of help in the diagnosis of functional night-vision defect. It should be noted that in apparently normal subjects not complaining of defective night vision it is not unusual to find a poor minimum form sense in tests with the dark adaptometer. Another helpful example of symptom inconsistency is that the figures obtained for the light and form senses may vary from day to day. This, in our experience, does not occur in any organic eye condition.

Men complaining of defective night vision and not showing any physical defect should be examined by a psychiatrist. Particular investigation should be made into the reaction to dark during childhood and the incidence of defective night vision in the soldier's unit and among his friends. In connexion with the suggestibility of the patient, the use of the phrase "night blindness" on any document to which the soldier has access should be strictly avoided. It is a fluent phrase easy to remember and quickly passed from mouth to ear.

Treatment of Defective Night Vision

Cases of functional defect of night vision are rarely amenable to direct psychiatric treatment, although they may be somewhat helped by rest and change of environment. Disposal should not be based on one investigation of the dark adaptation alone. It should be repeated several days later. If the minimum form and light senses are both within normal the patient should be reassured and returned to his unit in his original category. If the symptoms are severe and are supported by findings with the dark adaptometer he should be examined by a psychiatrist, and the ultimate disposal will depend on the psychiatric findings. In this connexion it is recommended that all those in one area complaining of defective night vision should be seen by one ophthalmologist, who is then in a position to detect a tendency towards "infectious spread" in any unit. Everybody has some difficulty in moving about in the dark, and the requirements of the Service or a danger of the complaint spreading may easily modify the suggested disposal to a more stringent one.

Diplopia

Diplopia is a common functional symptom. It may vary from a momentary slight separation into two images to a constant and well-defined double vision. To investigate the possibility of organic origin the usual tests for muscle paresis, muscle spasm, convergence weakness, concomitant squint, and muscle imbalance should be carried out. Most of the functional diplopia in the Army is found in the following types of cases.

(a) There may be a concomitant squint which has been present since childhood without giving rise to diplopia until recently. In civilian life it is very uncommon to find diplopia in an adult with concomitant squint. Yet such cases due to emotional stress are seen in this department almost every week. In these an organic condition is present, but the symptom-effect is not parallel with it. It is an interesting fact that suppression of one image that took place at, say, the age of 5 years and has persisted since should after two decades be functionally removed.

(b) There may have been a muscle imbalance which has persisted for years without causing diplopia. During these years the duction power has sufficed to overcome the tendency to squint. Under conditions of emotional strain this duction power may break down, when a small-degree horizontal or vertical squint with diplopia results.

(c) The functional disturbance may produce a spastic squint which is usually convergent. Three such cases seen in this hospital during the past year were due to spasm of the internal rect muscle. Ocular movements in these cases were good, if inclined to be jerky. The diplopia was found only in the central part of the field, both images coming together as the object was moved to the right or the left.

(d) The functional disturbance may produce a partial or complete loss of convergence. The diplopia is most marked at near vision. Some cases of partial loss of convergence are associated with exophthalmos, as will be mentioned later.

Treatment of Diplopia

Spastic squint and convergence loss may be cured by psychiatric measures alone. The results may be immediate and striking. In these conditions there has presumably been pre-existing organic disability.

Treatment of hysterical diplopia associated with concomitant squint or muscle imbalance that has become a squint is very difficult. I have not seen a case which has been cured by psychiatric measures alone. With these cases it is best to use both the psychiatric and the physical approaches. As a first measure the patient should be given some insight into the condition by the psychiatrist. Stress is laid on this being done before prisms or operation are tried. There are two reasons for this order in the treatment. In the first place, it prepares the patient to accept the later optical or surgical help. The operation cannot be guaranteed to have the necessary precision and the patient should know beforehand that he must contribute to the cure. In the second place, the patient's confidence in physicians is maintained. If he is sent to a psychiatrist at incomplete cure of his diplopia by surgical measures he is inclined to think that he is being passed to another doctor in view of the surgical failure; or, in his own words, that is "being messed about."

Should psychiatric, surgical, and prismatic treatment fail, patient should be made uniocular by placing a frosted glass before one eye. He should then be categorized "B1 (E only)." Even then he may have the last word by developing photophobia in the used eye.

Asthenopia

Ocular fatigue is fairly commonly functional in origin. In many cases there is a small refraction error, which, however, under other circumstances might not have been expected to cause any symptoms. Whether or not glasses should be prescribed for any individual case depends on the experience of the ophthalmologist. It is felt that there is over-prescription. Yet a fair balance is difficult in the midst of a large out-patient day, and the patient is often given the benefit of the doubt.

Phorias and convergence insufficiency should be examined for in these borderline cases. It should be remembered that a certain degree of exophoria at near vision is normal. It is invoked to explain asthenopia only if the positive duction power is not sufficient to control the degree of exophoria. The muscle balance and the duction powers are within normal limits and if after the use of suitable lenses the patient continues to complain of fatigue and strain, the case in the great majority of instances can be considered to be functional.

In considering asthenopia mention should be made of the poor lighting conditions found in many Army offices. This should be inspected periodically by the D.A.D.H. in conjunction with the ophthalmologist of the area.

Headache; Photophobia; Muscae Volitantes; Epiphora

These form a well-defined group of symptoms, all or some of which are often found in the same patient. In the production of some of these symptoms there is probably a disturbance of autonomic control. Unlike the functional diplopia and defective day or night vision which have been referred to as hysterical this group of symptoms, together with asthenopia, may more properly be defined as the chronic anxiety state with its manifestations.

The headache is usually retro-ocular or bitemporal, often felt on the side where one eye has had some chronic defect, such as amblyopia. Practically any adjective may be used by the patient to describe the pain. It may or may not be associated with the use of the eye. It is often evoked

exercise or excitement. The pain never wakens the patient during the night, although he may waken in the morning with it. This symptom, like all those mentioned in this report, is frequently associated with a change of environment. In many respects the photophobia runs parallel with the headache. It, too, may be unilateral, and be felt on the side on which, as the patient is aware, there is ocular inferiority. Dark glasses are often worn on days not much, if any, brighter than can be experienced on summer days in Britain. Their use appears to have a symbolic significance to the patient. As stated, *muscae volitantes* and epiphora are often associated with photophobia and headache. Like them, they are very variable in their incidence: days may pass without the patient experiencing them.

Before making the diagnosis of chronic anxiety state with ocular manifestations it is, of course, important to exclude organic disease. The media of the eyes, fundi, and tear ducts should be investigated.

It is interesting to note in connexion with the disturbance of autonomic control which is suspected to be the basis of this group of symptoms, that a number of cases presenting the syndrome of headache, epiphora, and photophobia later develop exophthalmos with a well-marked von Graefe sign. In them there is not necessarily thyroid enlargement or increase in pulse rate. As mentioned above, such cases may have a partial loss of convergence, with diplopia.

Treatment of Chronic Anxiety State with Ocular Manifestations

The treatment of chronic anxiety state with ocular manifestations is more satisfactory than that of ocular hysteria, and in many cases can be satisfactorily carried out by the ophthalmologist. The qualities required are patience, kindness, and directness. It is easy to advocate these qualities, though difficult to show them in the rush of the clinic. Nevertheless no good treatment of the chronic anxiety state can be carried out without them. There must be patience to listen to the man's story, to watch his mind during the examination, to evoke his past life and environment, and to interrogate his emotions so that the hidden anxiety state may be exposed. This must not be done in a gruff manner, otherwise the patient becomes defensive and more tongue-tied than ever. There must be directness to impress him that no disease of the eyes is present and to indicate the manner in which the symptoms arose. There are few patients who do not intelligently and emotionally respond to this treatment.

Summary and Conclusions

In this report mention has been made of (a) the two chief psychical conditions—hysteria and chronic anxiety state—which cause a variety of ocular symptoms; and (b) the differentiation of these functional symptoms from those produced by organic disease.

For clarity the psychosomatic processes have been described as well-defined entities. These processes are personality reactions, and although the individual may show a tendency to react in a certain way, personality is too complex for the reaction to be simple and uniform. In practice many a case does not fit into a clear-cut pattern. An obvious hysteric may develop symptoms described above as chronic anxiety state with ocular manifestations, while a case with hysterical symptoms in the eyes may have a well-developed chronic anxiety state. Moreover, the difficulty is not only as between one functional condition and another. Both an organic and a functional condition may be present in the same patient. Their relative significance in the production of the symptoms is of therapeutic importance. Only a very careful physical examination together with some considerations along the lines indicated above, and the experience of the examiner, can help disentangle the threads.

It may be of some help to think of organic and functional disturbances coexisting in one of three different ways: (1) The association in one patient may be fortuitous. (2) A functional disturbance may be superimposed upon an organic one, modifying or aggravating the symptoms. (3) The psychic disturbance leading to upset of ocular function may appear to be an integral part of the organic process. This is noticed in disseminated sclerosis. It is not unusual in this disease for the "functional" symptom to be the predominant one and to be present for a long period before the "organic" symptoms arise.

I would like to express my thanks to Brigadier C. W. Graham, Consultant Ophthalmologist, Brigadier G. W. B. James, Consultant Psychiatrist, M.E., Major J. M. M. Jacobs, and the staff of No. 2 Psychiatric Centre for their generous guidance and help. Many of the cases were diagnosed and treated in No. 2 Psychiatric Centre.

HUMAN FIBRIN AS A DRESSING FOR BURNS*

BY

R. G. MACFARLANE, M.D.

*Clinical Pathologist, Radcliffe Infirmary, Oxford;
Radcliffe Lecturer in Haematology, Oxford University*

The copious and continued oozing of fluid from a superficial burn is a curious contrast to the behaviour of an abrasion, which soon becomes covered by a scab of dried and clotted exudate. It is clear that the normal mechanism of haemostasis is unable to control the exudation of plasma from the capillaries at the surface of a burnt area. It is a temptation to think that the delay in healing of such burns as compared with abrasions of equal magnitude may be the result of this continued oozing, since in the haemorrhagic states even minute wounds may refuse to heal for weeks unless leakage of blood is stopped by suitable treatment. It is certain that in severe cases the loss of fluid from the burnt area may be so great as seriously to aggravate haemoconcentration, and a practical method of controlling this loss would be of clinical importance.

Attempts were made, therefore, to control this exudation by means that are usually successful in controlling the exudation of blood in the haemorrhagic states. To begin with, various coagulants, such as Russell viper venom and thrombin, were applied to the surface of burns, but any hastening of coagulation that was produced appeared ineffective.

It was observed that blisters forming soon after a burn usually contained masses of loose trabeculated fibrin that had no controlling effect on the exudation of fluid. The "blister fluid" that was drawn off and examined contained a further small amount of fibrinogen and often underwent secondary clotting in the test-tube, suggesting that the clotting mechanism was not seriously deranged. Unfortunately it was not possible to make quantitative estimations of fibrinogen and prothrombin on the exudate before it had partially clotted. Experiments with blister fluid showed that it differed little from the patient's serum. Titration of the immediate antithrombin, the progressive antithrombin, and fibrinolysin gave results essentially the same as those obtained with the blood serum. From these observations it appeared that the continued exudation of fluid might be the result not of defective coagulation but of a capillary defect, so that the local condition might be analogous to the continued bleeding in the purpura, in which coagulation is normal. No effect would therefore be expected from the mere addition of coagulants to the issuing fluid: as in the purpura, the flow must be stopped by mechanical means.

It was therefore decided to attempt to seal the burnt surface with some relatively impervious dressing. Human fibrin was chosen as the physiological ideal, and it was hoped that its presence might reproduce the conditions in traumatic wounds and encourage healing. After unsuccessful attempts to produce a sufficiently tough and adherent membrane by covering the burn with concentrated fibrinogen solution, or dried fibrinogen subsequently clotted by a spray of thrombin, it was decided to preform the fibrin membranes and apply them when required.

Preparation of the Fibrin Membrane

The technique that finally evolved was as follows: Human plasma was allowed to clot in flat shallow dishes. The ordinary photographer's earthenware developing-dish about 12 in. by 10 in. was found satisfactory. Before adding the plasma the dish was levelled with a spirit level in order to ensure even thickness of the membrane. About 450 c.cm. of plasma was used for each membrane, and this was mixed with 100 c.cm. of 1.18% CaCl₂ and 0.5 c.cm. of 1 in 100,000 Russell viper venom, in a large measuring cylinder. The mixture was rapidly poured into the dish and any large bubbles burst with a hot wire. Firm coagulation usually took place in from a half to one minute. The clotted plasma was allowed to stand for 30 minutes and was then covered with about 500 c.cm. of tap-water. By gently rocking the dish the clot was detached from the sides so that it floated freely in the water. It was

* A report to the Burns Subcommittee of the M.R.C. War Wounds Committee.

then covered with a sheet of blotting-paper cut to fit the dish, and this in turn by a sheet of perforated zinc of the same size. By pressure on this sheet much of the serum in the clot could be squeezed through the blotting-paper and perforations. Water and serum were then poured away, and by careful inversion the clot was turned out, lying on the blotting-paper and zinc. These were now laid on a draining-board, and the upper surface of the clot covered by another sheet of blotting-paper and perforated zinc. Pressure on this expressed the remainder of the serum.

On removing the blotting-paper the clot was found to have been compressed into a thin sheet of yellowish fibrin. This was carefully washed in water until white, and then pressed between sheets of dry blotting-paper. The finished membrane is a tough, elastic, glistening white sheet when wet; when dry it becomes transparent and brittle.

Sterilization of the Membranes

The membranes, suspended in saline in small screw-capped bottles, were usually treated by heat. Though they resist boiling, the fibrin becomes thickened and waterlogged and loses much of its elasticity. Heating to 80° C. for one hour or 70° C. for two hours was found to be less deleterious and to kill non-sporing pathogens incorporated experimentally in the fibrin, and this treatment was used throughout the clinical trials.

In Dr. Colebrook's laboratory experiments on sterilization by antiseptics and bacteriostatics were carried out. Small experimental membranes were made from plasma to which cultures of *Staph. aureus*, *Bact. coli*, streptococci, and *Ps. pyocyaneus* had been added. These infected membranes were incubated for varying periods in different concentrations of C.T.A.B. (cetyltrimethylammonium bromide), 2:7-diaminoacridine, dettol, sodium sulphacetamide, sulphanilamide, etc. The pieces of fibrin were then removed from the solution, washed in sterile water, and planted out in broth. It was found that the C.T.A.B. completely dissolved the fibrin in 24 hours, and even after three hours the membrane was partly destroyed. The organisms were not killed by three hours' immersion in 1.5% C.T.A.B. 24 hours' immersion in 30% dettol sterilized the membrane, but also partly destroyed it. Sulphanilamide (2%) and sodium sulphacetamide (20%) did not damage the membrane, but organisms were still viable after 24 hours.

The 2:7-diaminoacridine stained the membrane a bright red, but did not impair its properties. 24 hours' immersion in this substance killed all the organisms named when the dye was in concentration of 1 in 1,000. When it was reduced to 1 in 10,000 the coliform organisms and staphylococci remained viable.

Preservation of the Membrane

All the membranes used in the clinical trials had been "pasteurized" by heat. One, in addition, had been preserved in 1 in 10,000 diaminoacridine. After two or three weeks' immersion in saline, even in the refrigerator, membranes begin to lose their toughness and finally to disintegrate. Various preservatives have been tried without effect. Freezing the membranes retards the deterioration to some extent. In the dry state they appear to keep indefinitely and to regain their elasticity when soaked in water. They are so brittle when dry, however, that it is almost impossible to handle them without breaking, and as a method of preservation it was found impracticable.

Application of the Membranes

Several methods of sticking the membranes to the burnt surface by means of freshly formed fibrin were used, all of which gave firm adhesion. At first the burnt area, after being cleaned, was sprayed with fresh human plasma to which enough calcium chloride had been added to produce clotting in three or four minutes. The membrane was then spread over the surface, smoothed down, and the edges trimmed with scissors. Subsequently plasma was applied to the burn as before, but coagulation was produced by a solution of thrombin, in which the membrane had been soaked before application. In one case the membrane was applied over a burnt surface that had been covered with powdered fibrinogen, the membrane having been moistened with thrombin. This latter modification was not so successful, as the powdered fibrinogen contained air, which formed bubbles as it went into solution.

Clinical Results

Eight cases of accidental burns and two experimental burns have been treated by the application of about 17 sq. ft. of preformed membrane made from human fibrin. Two cases were in the Radcliffe Infirmary, under the care of Dr. J. M. Barnes; the remainder were at the Royal Infirmary, Glasgow, under the care of Mr. A. M. Clark and Dr. L. Colebrook. A brief summary of these is given below.

Case 1.—Male aged 31, admitted July 26, 1941, three hours after petrol burns of hands and forearms and circumference of right leg. The burns were cleaned under general anaesthesia; the hands and arms were encased in plaster and the leg was covered by a fibrin membrane over a film of recalcified plasma. A small area of the leg that could not be covered with fibrin was tanned. Within three hours the membrane had become transparent and a few drops of fluid exuded through it. For the next three days the membrane remained intact and firmly adherent, but the small tanned area began to suppurate. Then the centre part of the membrane softened and was digested, and culture from this area showed infection with *Staph. albus*. The membrane was removed, the area which was then granulating was powdered with sulphanilamide and penicillin, and a new membrane applied. This dried into a transparent scab, which began to flake off from the edge as new epithelium appeared. Healing was complete in 17 days. The plasters were removed from the hands and arms a day later and here also healing was complete except for a few small blisters.

Case 2.—Male aged 19, admitted May 4, 1941, 24 hours after sustaining severe burns, multiple fractures, and lacerations in a aeroplane crash. The burns were treated by various methods. About 10 weeks after admission fibrin membranes were applied to four suppurating areas on legs and body. One of these was allowed to dry in air, and remained intact for three weeks, though a small amount of pus formed under a fold that had become detached. When removed there was evidence of active healing beneath it, and a second membrane was applied; but there was considerable formation of pus, and it was removed 12 days later without much evidence of further healing. Two other membranes were applied to suppurating areas on the chest and shoulders, and were kept moist by a oiled-silk dressing. In both cases the fibrin was completely digested over the whole of the raw area within 24 hours of application, and each area then healed within a few days without further application.

Case 3.—Male aged 14 months, admitted Oct. 7, 1942, one hour after extensive scalding of back and thigh with boiling water. The burnt area was cleaned under general anaesthesia, and the upper two-thirds covered by a fibrin membrane, over plasma and thrombin. Sulphanilamide cream was applied to the remainder of the burnt area. During the next two hours there was some exudation of fluid from the area not covered by the membrane, though the membrane itself was dry. Two days later there was some elevation of small areas by collections of fluid beneath the fibrin, and five days after application part of the centre had been digested. Healing appeared to be almost complete under the peripheral part of the membrane that remained. Seven days after the burn the membrane had flaked off and healing was progressing, except in the centre of the area originally covered, where there was a brown slough. The area of the burn treated with sulphanilamide cream appeared to be healing equally well. The sloughs finally separated nearly a month after the burn, and it was decided to graft that area.

Case 4.—Male aged 5, admitted Oct. 12, 1942, two hours after scalding scapular areas and buttocks with hot water. After cleaning, membranes were applied to the two burnt areas on the left side, those on the right being treated with sulphanilamide cream. Two days later it was found that the membranes had stuck to the gauze coverings and were only adherent in places to the burnt areas. There had been some discharge from this side. Four days after application the membranes became detached completely, leaving a clean surface that looked very similar to that on the other side treated with cream. Healing on both sides was complete within two weeks.

Case 5.—Male aged 27, seen as an out-patient on Oct. 12, 1942, six hours after petrol burn of dorsum and fingers of right hand. The burnt area was cleaned and covered with fibrin membrane cut to fit, and bandaged over gauze. The membrane dried into a hard scab, which remained *in situ* for 10 days, when it separated, showing complete healing beneath.

Case 6.—Male aged 2, admitted Oct. 14, 1942, two hours after scalding chest and left arm with hot tea. After cleaning, a small area on the arm was covered with membrane, the rest being dressed with sulphanilamide cream. Within an hour of application the membrane became dry and transparent. Unfortunately the child died suddenly 11 hours later.

Case 7.—Male aged 5, admitted Oct. 15, 1942, two hours after scalding left arm, back left side, and left leg with hot water. After plasma transfusion the area was cleaned, the arm being covered with a fibrin membrane, the remainder dressed with sulphanilamide

ream. The membrane remained intact for eight days, when it separated. The lower part of the arm had healed; all the rest of the original burnt areas were covered by brownish sloughs, which separated 11 days later, leaving granulating surfaces, which it was decided to graft.

Case 8.—Female aged 27, seen as an out-patient 24 hours after cauldng leg with boiling water. After cleaning, a membrane was applied, with almost immediately relief of pain. The membrane dried up, but two days later a small area in the centre became ligested. Healing proceeded rapidly under the intact parts of the membrane, and was complete in 12 days.

Experimental Burns

Burns were produced on the upper part of the extensor surface of the forearms by the application of the end of a copper cylinder, 1 in. in diameter, through which hot water was flowing. The apparatus was devised by Prof. R. A. Peters Leach, Peters, and Rossiter, (1943). The results are set out in tabular form below:

Subject I (R. G. M.)

Time	Left Arm	Right Arm
0	56° C. applied for 45 seconds. Blistering and detachment of cuticle over whole area. Covered by fibrin membrane and left exposed to air. Immediate relief of pain.	56° C. for 50 seconds. Blistering and detachment of cuticle over whole area. Covered by fibrin membrane, then by oiled silk to keep moist. Pain relieved.
5 hours	Membrane has dried into hard translucent film where attached to skin; soft and pliable over burnt area. No pain.	Membrane unfortunately torn off when boarding a moving train. Area oedematous and inflamed. Dressed with castor oil and sulphalamide.
24 hours	Membrane dry and firmly attached. No oedema. No other covering. No pain or discomfort.	Painful and tender. Discharging pus. Redness over area 3 in. in diameter. Oedema over area 4 in. in diameter. Re-dressed, with relief of pain.
48 hours	Membrane covered with dry gauze and strapping to prevent accidental detachment. Perfectly comfortable and painless.	Painful and swollen. Culture: <i>Staph. aureus</i> .
4 days	Apparently healed under membrane, which is now quite dry.	Oedema of whole forearm. Dressed with penicillin.
6 days	Membrane flaking off, leaving new epithelium.	Ester, but still swollen and painful. Re-dressed as before.
8 days	Completely healed.	Better: beginning to dry up.
10 days	—	Scab flaking off, leaving new epithelium.
12 days	—	Healed.
2 weeks	—	Obvious scar.
9 months	No scar.	—

Subject II (L. C.)

Time	Left Arm	Right Arm
0	56° C. for 60 seconds. Detachment of cuticle. Dressed with sulphalamide cream under oiled paper. Relief of pain.	56° C. for 60 seconds. Detachment of cuticle. Dressed with fibrin membrane. Relief of pain.
24 hours	No pain or swelling. Re-dressed as before.	No pain or swelling. Some leakage of fluid beneath loose corner of membrane.
48 hours	No pain, no swelling. Re-dressed as before.	No pain or swelling.
4 days	Some inflammation and oedema round burn, which is covered by a film of yellow exudate. Allowed to dry in air.	Membrane dry and firm. No inflammation or oedema.
6 days	Dry and comfortable.	Some oedema and discomfort. Infected with <i>Staph. aureus</i> and diphtheroids. Fibrin membrane digested. Dressed with penicillin.
9 days	Hard scab.	Hard scab.
11 days	Healed.	Healed.
12 days	—	Healed.

Conclusions

It is clear that the covering of burnt areas with an adhesive membrane of human fibrin is a comparatively easy procedure. From the results, however, it will be seen that any clinical advantage over orthodox treatment is so slight as to make the trouble involved in preparation and application hardly worth while. The membranes relieve pain rapidly and form comfortable dressings, but the same can be said equally of many other applications. They may, to a certain extent, reduce fluid loss during the first 24 hours, but it would probably be more economical to transfuse the patient with the plasma required to make the membrane. In the cases that became infected the membranes were rapidly lysed. In favourable cases

the membrane dried into a scab, and healing proceeded beneath this. Even so, however, healing did not appear to be much more rapid than was the case in other areas treated differently.*

The problem of the fluid loss from burnt areas still remains, and its causation is of obvious interest and importance. That it is due mainly to paralysis or disordered function of the capillaries seems probable. Attempts to restore this capillary function might be therapeutically profitable.

I wish to thank particularly Dr. L. Colebrook for his kindness and advice in Glasgow, Prof. J. W. S. Blacklock for providing laboratory accommodation, and Dr. J. M. Barnes for allowing me to apply this form of treatment to his cases in Oxford. I am also indebted to Prof. R. A. Peters for advice and interest. My gratitude is due to the Medical Research Council for financial assistance and to Glaxo Laboratories Ltd. for the gift of special apparatus that was used in the experiments on blood coagulation and the preparation of fibrin, thrombin, and fibrinogen.

OUTBREAK OF SANDFLY FEVER IN TWO GENERAL HOSPITALS IN THE MIDDLE EAST

BY

Lieut.-Col. E. R. CULLINAN, M.D., F.R.C.P.
Officer in Medical Division, a General Hospital, M.E.F.

AND

Major S. R. F. WHITTAKER, M.B., M.R.C.P.
Medical Specialist, a General Hospital, M.E.F.

From July 28 to the end of Oct., 1942, there was a severe and explosive outbreak of sandfly fever among the staffs of two general hospitals and among the patients admitted to one of them. These two hospitals came to a new station during the last week of July. They occupied newly made sites, side by side. Hospital A took over the site and patients of another hospital which had been working since early June, 1942. Hospital B did not receive patients until the beginning of September.

Within a few days of arrival members of the staff of both units began to get sandfly fever, other ranks being more affected than officers and sisters. Later, patients who had been admitted to Hospital A for other complaints contracted the disease. By the end of August the epidemic had become serious. It ceased abruptly at the end of October.

Incidence of Sandfly Fever among Unit Personnel

Several of the "other ranks" had two or more attacks, which explains why the total number of admissions exceeded the

* Since submitting this report I have learned through the Medical Research Council that Ingraham and Perring of Harvard Medical School are using fibrin membranes "plasticized" by glycerol to prevent them becoming brittle, and sometimes backed with cotton. These improved membranes have given good results as a dressing for burns, and particularly as a dural substitute in brain surgery. Fibrin has also been used as a haemostatic. I have used small pieces of fibrin membrane soaked in thrombin as a haemostatic dressing for haemophilic cases with very encouraging results.

total strength. Even so, the majority of N.C.O.s and men suffered from the disease.

Hospital A

	Total Admissions, including Readmissions	Average Total Strength
Officers	8	30
Sisters	20	80
Other ranks	282	240

Chart 1 shows the number of other ranks admitted each day and the number remaining in hospital. It will be seen that for fifteen consecutive days from Aug. 27 to Sept. 10 there were over 70 men in hospital. The peak was reached on Sept. 2

(87 men). The epidemic occurred at a time when the hospital was busy. In all, 1,910 patients had been admitted to the medical division alone between July 29 and Sept. 30.

Hospital B

	Total Admissions, including Readmissions	Average Total Strength
Officers	12	28
Sisters	12	30 to 80
Other ranks	171	210

Chart 2 shows the figures for Hospital B. The epidemic was less severe than at Hospital A, but was nevertheless serious. The peak was reached on Aug. 26, when there were 50 men in hospital. In addition to the 171 cases admitted to hospital at least 30 more N.C.O.s and men were treated in their tents. The unit was not working to capacity, since patients were not received until the beginning of September.

Incidence of Sandfly Fever among Patients Admitted to Hospital A for Other Diseases

At Hospital A 365 patients who had been admitted for other diseases developed sandfly fever. Chart 3 shows the daily incidence of the disease and also the total number of patients in hospital. It will be seen that there were two periods when

the total number of patients in hospital was greatest—that shortly after the admission of fresh convoys of patients.

The distribution of the disease in the wards of Hospital is interesting (see Chart 4). With the exception of wards 10, 11, and 12, which were not in use until October, all wards contained approximately the same number of patients throughout the period of the epidemic. The incidence of sand fever was greatest in surgical wards 1 and 6, and lowest medical wards 3 and 4. Ward 1 was a stone ward, where ward 6 was a group of tents. Hence it appears that incidence did not depend on whether the wards were "hutter" or "tent." It will be seen from Chart 4 that the situation of the ward was important. The camp was newly constructed

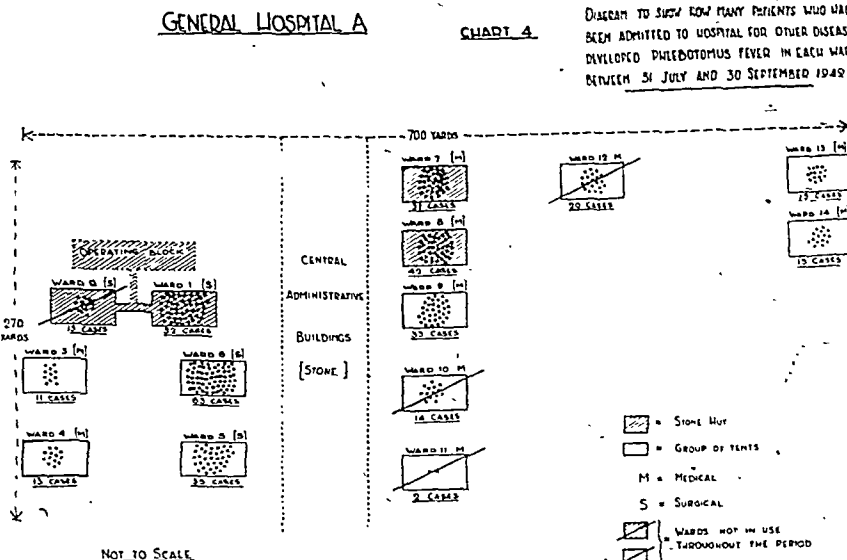

and, although it was largely tented and widely dispersed, there were some huts built of stone and the ground was stony. Much stone and rubble lay around and near the buildings. Where the incidence was greatest—around wards 1 and 6 and also around wards 8, and 9—the incidence of the disease was high. Where it was least—around wards 3 and 4 and particularly 13 and 14—it was low. This accords with the known habitat and the flight of the phlebotomus.

Clinical

The clinical picture was classical. One of us (E. R. C.) has seen many outbreaks of "short-term fevers," but none in which the symptoms and signs agreed so exactly with the standard descriptions.

CHART 4

DIAGRAM TO SHOW HOW MANY PATIENTS WHO HAD BEEN ADMITTED TO HOSPITAL FOR OTHER DISEASES DEVELOPED PHLEBOTOMUS FEVER IN EACH WARD BETWEEN 31 JULY AND 30 SEPTEMBER 1942.

was pain in the thighs and along the line of the ribs, or dysuria. When the patient reported sick the temperature was usually raised

incubation period in most instances was unknown. In a few there was reasonable evidence that it was as short as 3 days. Cases occurred exactly 3 days after men had arrived from another country.

The onset was usually abrupt with severe headache—particularly supra-orbital headache—pain in the back, and fever. There was pain behind the eyes, especially on movement of the eye. Sometimes the

to 102° or 103°, but occasionally the initial symptoms preceded the fever by 14 hours. Conjunctival congestion and pain on pressing the eyeballs were a common finding. The fever lasted from 1 to 8 days, but in most cases from 3 to 4 days. In about 10% there was a short secondary rise of temperature, usually about the 6th or 7th day. The initial temperature was sometimes over 105°, and the prostration was great. Many of the patients appeared very ill, and in a few instances the photophobia was agonizing. Drowsiness was sometimes pronounced, and in one patient the cerebrospinal fluid contained 110 lymphocytes per c.mm. and 90 mg. of protein per 100 c.cm. The colloidal gold test was negative. The disease was often followed by debility and depression. There were no complications and no deaths. Members of the hospital staff were usually off duty for 7 to 12 days and sometimes longer. Several senior N.C.O.s who had never been in hospital before were affected. Some of the patients who had previously suffered from malaria remarked that sandfly fever "knocked them out" far more than malaria.

The classical clinical picture and the known heavy infestation of the camp with the phlebotomus left the diagnosis in little doubt. The *Aedes aegypti* had not been seen, and dengue could be excluded. Neither malarial parasites nor spirochaetes were seen among the many hundreds of blood slides examined.

Immunity

It is sometimes said that one attack of sandfly fever confers a sound and lasting immunity. This is not our experience. It is true that both hospitals were newcomers to the district. Hospital B had recently arrived from England, and although Hospital A had been in the Middle East for a considerable time, it had been in a district where the disease was unknown among the staff. In the present epidemic 15% of the N.C.O.s and men had two attacks, and some had three attacks, during the three-months period, at intervals ranging from two weeks to three months. The initial symptoms of the later attacks were often as severe as those of the first attack, but the illness tended to be shorter. Between the attacks the men were on duty and felt fit. The attacks ceased abruptly at the end of October. It seems clear that second attacks were not relapses but fresh infections. It is possible that men succumbed to a fresh infection before immunity had developed or that a second attack was caused by a different strain of infection. It appears, however, that one attack conferred little or no immunity in this area.

Control

Antimalarial precautions were strictly observed by the personnel of both units. At Hospital B from September onwards all tents were "flitted" in the evening and half an hour before reveille. Men were ordered to be properly clothed until the sun was well up. These measures had little effect on the incidence of the disease.

At Hospital A an attempt was made to stem the tide of the epidemic among patients in hospital for other diseases. It was obviously impossible to deal with the breeding-grounds of the phlebotomus. This would have entailed concreting or asphaltting the whole site. Acting on the assumption that the phlebotomus starts biting at about 9 p.m. and continues until the sun is well up, the following measures were adopted early in September and rigorously enforced:

Every patient suffering from or suspected to be suffering from phlebotomus fever was nursed under a sandfly net day and night until he was afebrile. All other patients had their nets lowered from one hour before sunset until the wards had been "flitted" the following morning. Every ward and annexe (including latrines) was "flitted" three times a day—just before waking the patients, before the evening lowering of the nets, and at "lights out."

A glance at Chart 3 suggests that these measures had little or no effect on the incidence of the disease.

A suggestion was made that the infection might be controlled in the wards by burning pyrethrum powder throughout the night. The epidemic ceased, however, when this suggestion was made.

If there should be another epidemic in the future, it is proposed to carry out a controlled experiment, using the burning powder in two out of four tents in each group of tented wards.

SANDFLY FEVER AND THE RHEUMATIC SERIES

BY

R. L. FERGUSON, M.B., Ch.B.

Surg. Lieut., R.N.V.R.

The similarity between sandfly fever and influenza is generally known, though I have not heard of this fever being associated with the rheumatic series. Towards the end of the Sicilian campaign I had two cases of sandfly fever, and one case which, for want of a better diagnosis, I have named "pyrexia of rheumatic origin"; all three cases bore a remarkable similarity—so much so that I consider them worthy of record.

Case Histories

Case 1.—Diagnosis, sandfly fever. This patient, a leading stoker aged 22, went ashore in Sicily on the evening of Aug. 5, 1943, for recreational leave. On the evening of the 9th he reported to the sick bay, stating that he felt as if he had influenza. His temperature was 102° and his pulse rate 96. He complained of general stiffness of his limbs, intense pain behind the eyes, slight epigastric discomfort, and pain in his abdomen which radiated to the loins. He vomited twice during the evening, before reporting. On examination he was flushed, his conjunctivae were injected, and his tongue was furred. He was suffering from numerous insect-bites on his legs and trunk. His temperature slowly resolved, as is shown on the chart, and his symptoms abated with the diminution of fever. He was given 10 minims of tinct. opii three times a day, and tinct. iodi mistis to the insect-bites; he was also given A.P.C. tablets for the headache.

FIG. 1.—Temperature Chart of Case 1.

Case 2.—Diagnosis, sandfly fever. A leading stoker aged 24 went ashore in Sicily on the evening of Aug. 5, 1943. On the morning of the 11th he reported to the sick bay, complaining of intense supra-orbital headache and stiffness at the back of the neck and on the shoulders. He said that he had been feeling "off colour" for 24 hours previously. He complained of general lassitude and tiredness, but otherwise felt all right. His temperature was 101° and pulse 80. Towards the evening he sweated profusely, his face became swollen, and he suffered from severe conjunctivitis. He found difficulty in resting quiet in bed because of generalized aches and pains. There were a few isolated insect-bites on his trunk and legs, and he suffered from nausea and could not take his food. On the 13th the conjunctivitis cleared, but the headache persisted until the 18th. The generalized aches and pains in his limbs settled on the evening of the 15th, and from then on he appeared to be much better. He began taking his food normally, and finally was allowed up on the evening of Aug. 19, after eight days' sickness. He was treated with tinct. opii 10 minims b.d., aspirin and phenacetin aa gr. 5 S.O.S., luminal gr. 2, to help his insomnia.

FIG. 2.—Temperature Chart of Case 2.

Case 3.—A leading seaman aged 20 reported to the sick bay on the evening of Aug. 11, 1943, stating that he was suffering from an influenzal attack; he had not been ashore for some time. He said that he had been feeling ill all day, but thought that he would

"try and stick it out." He said he suffered from aches and pains in his back and legs, especially in the muscles of the calf and in both knee-joints. He also had a severe frontal headache. He said that he had had rheumatic fever eleven years previously, and since then had suffered almost every year from similar attacks. In civilian life he went to bed and was attended by his doctor; the last attack was two years previously. On examination his temperature was 104.8° and his pulse 120. The only physical sign detected was a soft presystolic mitral murmur, which was not heard four days after the onset of the pyrexia. He was confined to his hammock and given mist. sod. sal. gr. 20 and luminal gr. 2. The following day he was given mist. sod. sal. gr. 20 and aspirin gr. 10 t.d.s. On Aug. 14 all medicines were discontinued, and he returned to duty quite well.

FIG. 3.—Temperature Chart of Case 3.

Owing to the exigencies of the Service at the time it was only possible to obtain blood films from each of the patients on Aug. 12, 1943, and examine them microscopically in a large ship, in order to exclude malaria or leishmaniasis; blood counts were not done. No parasites were seen in a careful examination of the slides. Paratyphoid, dengue fever, and influenza were all considered, and were rejected as improbable. Cases 1 and 2 were diagnosed as phlebotomus fever, and Case 3 as pyrexia of rheumatic origin. These patients suffered from intense supra-orbital headaches and generalized "rheumatic" pains, which varied in intensity. In all three cases there was absence of severe gastro-intestinal symptoms such as may be expected in the later stages of sandfly fever. The pyrexial period varied between 3 and 8 days. Bradycardia was not noticed in either of the cases of sandfly fever.

Conclusion

Case 3 resembled no particular syndrome with which I am familiar, but appeared to be related to the rheumatic series of diseases.

The cases resembled one another closely, and, by coincidence, occurred at the same time.

Cases 1 and 2 were diagnosed as phlebotomus fever because of the short duration of pyrexia, the presence of insect-bites, and the symptomatology. The fever, as is known, is caused by a virus introduced by the bite of *Phlebotomus papatasi*, which is present in large numbers in Sicily from May to October.

Almost constant "action station" routine caused the patients discomfort owing to the stuffy atmosphere in the ship, but it was possible to treat such cases of high pyrexia on board a destroyer provided that the patient was nursed efficiently.

According to Wenscher (*Dtsch. med. Wschr.*, 1942, 68, 984) neurological signs aid in the early diagnosis of typhus. The first indication is sudden high rise in temperature, accompanied by a typical and unusually stubborn headache which responds only slightly to analgesics. An additional sign is hardness of hearing, which occurs in almost all cases. If these signs are accompanied by speech disorders and the characteristic twitching of the perioral muscles the diagnosis of typhus exanthematicus is assured even without a distinct exanthema. Therapy consists in relieving the pressure. Apathy or restlessness responds quickly to lumbar puncture; circulation and respiration improve and the distressing headache disappears. Along with the essential support of the cardiovascular system, the main therapeutic concern is the prompt reduction of increasing pressure in the c.s.f. For this reason strophanthin should always be given in strongly concentrated glucose solutions, which exert a dehydrating action. After damage to the vasomotor and respiratory centres, the next most important danger is the occurrence of bulbar paralysis.

Medical Memoranda

An Unusual Form of Ectopia Testis

Sir John Thomson-Walker (1936) quotes Eccles (1903) as considering it extremely doubtful if the testis is ever spontaneously passed into the upper part of the thigh through the femoral ring. The following is the record of such a case.

Cpl. A., aged 43, was admitted to hospital with the diagnosis of right inguinal hernia. Seven years previously, while engaged in heavy work, he felt a sharp pain in the right groin followed by appearance of a lump; the swelling had remained there since. Examination showed a swelling the size of a hen's egg in the right groin, over the junction of the middle and inner thirds of inguinal ligament. The swelling was not reducible, felt cystic, was attached to the deep tissues. The right testicle was present on the scrotum, the left half of which was empty.

Operation showed the swelling to be an ectopic testis which descended through the femoral ring and canal, and had all coverings of a femoral hernia. A hydrocele was present; was aspirated, and the testis then made to retrace its path, femoral ring being exposed from above as in Lotheissen's operation. Dissection revealed a hernia of the congenital type, the neck of which was very narrow. The fluid in the sac had been restricted to the distal extremity by the constriction to the sac as it passed through the femoral ring, forming a hydrocele of the hernial sac. The spermatic cord consisted only of a fine bunch of vessels, the testicle itself being extremely atrophied.

Two interesting features are that the testis had passed through the femoral ring to gain the upper part of the thigh, and that both normal and ectopic testes were on the same side, the latter being justifiable that one testis found its way through the femoral ring because the normal passage through the inguinal canal was already occupied.

My thanks are due to Prof. R. C. Alexander, Surgical Director for the area, for permission to publish this case.

T. C. SKINNER, F.R.C.S.Ed
Surgeon, E.M.S.

Recovery after 700-foot Fall

The following case would seem unusual enough to merit being placed on record.

CASE REPORT

A well-built paratroop pupil aged 25, weighing 11 st., was parachuting from an aircraft travelling at 80 m.p.h., at a height of 700 feet, into a 10 m.p.h. wind. Unfortunately, although the parachute came out of its pack, the canopy did not develop properly, with the result that the pupil landed some 10 seconds later on a ploughed field, dropping at a speed which must have been in the region of 50 m.p.h. When examined a few seconds later he was found to be still alive and just conscious. He was lying on his left side in a crouched position, with his knees drawn up towards his chin. The pulse rate was 70 a minute and weak, breathing was shallow and difficult owing to much mucus being brought up, and there was a small amount of thin yellowish fluid exuding from his right ear. Physical examination showed no obvious signs of fracture or paralysis. The pupils were equal and of normal size.

A "tubonic" ampoule (morphine hydrochloride gr. 1/3, atropine sulphate gr. 1/120) was given, following which he was put on a stretcher. A few minutes later he became very restless, and as he was now trying to move his arms and legs he had to be strapped securely to the stretcher during transit to hospital. Next day he looked very ill, but was cheerful and mentally clear, showing signs of disorientation or amnesia. He could move his arms and legs without difficulty and his excretory functions were normal. Two days later the improvement was so marked that he was considered fit for x-raying, when it was discovered that he had a compression fracture of the 12th thoracic vertebra. After immobilization in a plaster cast progress was satisfactory and uninterrupted.

COMMENTARY

Partial failure of a parachute is extremely rare and is almost as unique as this man's survival of the accident, which was undoubtedly an extraordinary escape, especially in view of the fact that all previous occurrences of this nature had resulted in instantaneous death either from multiple injuries or from fractured cervical vertebrae.

Reliable eye-witnesses of this descent were of the opinion that the degree of inflation of this soldier's parachute was slight and his fall so rapid that he could not possibly escape death. It is thought that he landed on one foot and fell six ways, thus preventing the full force of his landing being transmitted through the legs and spine to the base of the skull.

high would have resulted in a fracture in one or more of these places as in the other cases.

We desire to thank Squad. Ldr. J. D. Milne, R.A.F., and Major B. Davies, I.M.S., for permission to publish this case report. It would like to emphasize the co-operation between all the medical services concerned.

F. G. NEILD,
Capt., R.A.M.C.
C. M. MACKENZIE,
Flight Lieut., R.A.F.V.R.

Unusual Burn of Cornea from Molten Wax

Mr. H. Sewell Sims, of Palmer's Green, asked me to see a male patient whom he had attended the previous day. She complained of loss of sight after flicking out a lighted wax taper with which she had lit a gas stove, when she said some wax flew between the eyelids. There was no reaction to this foreign body, and the appearance of the cornea was quite normal till, on examination through a loupe, a perfectly transparent layer of wax was seen covering two-thirds of the cornea, which looked as if it had a contact lens lying on it. Until this was removed the cornea did not stain with fluorescein; afterwards approximately two-thirds stained, but the erosion was quite superficial. The wax was removed with a blunt instrument under cocaine, when the vision at once improved from one-tenth to one-third of full vision. Atropine and castor oil were instilled and the eye bandaged. The effects of the cocaine passing off, the eye wept profusely and was very painful. With the ophthalmoscope there was seen a fine line in the cornea, which marked the limit of where the wax had

rested. In spite of the extent of the lesion it had no depth, only the epithelium being affected. It is quite feasible that it acted as molten metals often do—forming a cast of the front of the eye, with a fine layer of protective vapour between. Usually, of course, the lids close so quickly that the cornea escapes injury.

Considering the risks that housewives run several times daily, it really is remarkable that injuries of a similar nature from splashes of boiling fat are not more common. Würdemann (1932) mentions boiling soap, fat, or lard as being possible causes of burns. Sir Stewart Duke-Elder (1938) makes no mention of this in his *Textbook of Ophthalmology*, though there is a diagram of a case of Mr. Doggart's which rather resembles this class of burn—a case of keratoconjunctivitis due to mustard gas. Haab (1909) has a plate in his *Hand-Atlas* showing a lime-burn of the cornea, which is more or less the same in appearance. Fuchs (1933) does not mention it.

Figs. 1a and 1b show the appearance after removal of the wax. Fig. 2a the line of demarcation, which, however, had entirely disappeared three days afterwards, when the eye was quiet and the vision normal again. Figs. 2b and 2c show the area stained by fluorescein. On the third day there was no staining, and the lesion had healed.

SYDNEY TIBBLES, L.R.C.P.S.E.,
Late Refractorist, Royal Hospital, Richmond.

Reviews

FRACTURES

Pictorial Handbook of Fracture Treatment. By Edward L. Compere, M.D. F.A.C.S., and Sam W. Banks, M.D. (Pp. 351; illustrated, 275) Chicago. The Year Book Publishers; London H. K. Lewis and Co. 1943.

Fractures. By Paul B. Magnuson M.D. F.A.C.S. Fourth edition, revised. (Pp. 511; illustrated 308.) London. J. B. Lippincott Company. 1943.

It is noticeable that the large number of textbooks on fractures which have appeared within recent years coincides with improvement in the results of treatment which has come about following segregation under specially trained staffs. Not all fractures, however, can be dealt with in special units, and it is necessary for both general surgeons and practitioners to be familiar with the most effective methods of reduction, fixation, and after-treatment. The scope for textbooks of fracture treatment is therefore wider than ever. The *Pictorial Handbook of Fracture Treatment* needs no apology such as we find in the preface. It is an excellent little manual and the pictorial part is particularly good—e.g., Fig. 130, p. 265, illustrates the method of production as well as the stages of treatment of "bumper" fractures; while Fig. 151, p. 295, depicts the way in which Colles's fracture and fractures of the os calcis and lumbo-dorsal part of the spine are produced. Fig. 163, p. 313, claims to depict Böhler's method of reducing a flexion compression fracture in the dorsal spine, but the credit for this method of treatment should, we believe, be given to Watson-Jones of Liverpool, and it is not usually desirable to anaesthetize the patient. Fractures of the patella are well done—it is pleasing to notice that the author does not support a recent radical and quite unjustifiable tendency to excise the simple transverse variety. Fractures of the skull may be thought to be rather briefly dealt with, but these fractures usually constitute a minor part of head injuries calling for treatment, and the surgical treatment—as opposed to first-aid treatment—of skull fractures may reasonably be considered to be beyond the ambit of this book. The book can confidently be recommended as a modern and well-illustrated outline of fracture treatment.

Like most new and the recent editions of older textbooks of surgery which have appeared in the last few years the fourth and latest edition of Magnuson's *Fractures* shows the influence of the war, and efforts have been made by the author to render the book more useful to surgeons in the Services. It is not surprising, therefore, that the principal additions deal with transportation and the early treatment of compound fractures. Written clearly in rather dogmatic style and well illustrated by line drawings and x-ray photographs this textbook is a straightforward guide which should be particularly helpful to medical students, practitioners, young surgeons generally, and Service medical officers. The line drawings, of which there is an abundance, appealed to us especially, as they indicate very clearly the steps in treatment of particular fractures—e.g., the method of reducing supracondylar fracture of the humerus (Fig. 5, p. 101)—a series of drawings showing the manipulations necessary and the reason for them. We are glad to find that the term "Pott's fracture" is still used despite a recent tendency noticed in some quarters to discard it. We disagree with the statement (p. 429) that "every patient with a skull injury accompanied by coma should be kept flat in bed at all times for a minimum period of two weeks." Nursing these patients with the head raised lowers intracranial venous congestion and has proved more effective; but in general the sections on skull fractures and their complications and those on fractures of the spine are as well done as the remainder and bulk of the book. Of the recently published books on fractures—of which there has been almost a spate—this is certainly one of the best.

FOOD POISONING

Food Poisoning: Its Nature, History and Causation; Measures for its Prevention and Control. By Elton B. Dewberry. Foreword by Gerald R. Leighton, M.D. In three parts, with appendices. (Pp. 166; illustrated, 151.) London: Leonard Hill Ltd. 1943.

Food poisoning is a complicated and extensive subject, but within 180 pages the author has covered its main features. The book is severely handicapped by being a compilation from other sources and not by an author who has himself investigated

the various problems involved. In many cases the original papers have not been consulted, while the views quoted may require modification, even by their authors, in the light of new experience.

The book is clearly written and arranged, while the numerous photographs of the chief workers in this field add to the interest. On the whole it has a high degree of accuracy, and its chief defect is some inequality of treatment. Botulism is given a very extended description, but, in particular, the author fails to realize the importance of staphylococcus food poisoning, and his description—confined to some three pages—is entirely inadequate and gives very little information. He also fails to draw the fairly sharp distinction which occurs in practice between outbreaks due to the ingestion of living bacteria and those in which the symptoms are of the toxin type. The distribution of *Salmonella* organisms in the animal kingdom is dealt with, but a great deal of importance is omitted, although this is of very great significance in connexion with the causation of food poisoning. The same importance attaches to the distribution in Nature of the various strains of *Salmonella* and the distinctions between the types, and very little information is given on this head.

In addition to bacterial food poisoning, chapters are devoted to contamination of food by poisonous metals, poisonous plants, poisonous fish and shellfish, and food allergy. In an appendix is reproduced the Ministry of Health's memorandum on steps to be taken by the M.O.H. when food poisoning occurs, with the Ministry's note on the identification of *Salmonella* types.

While the book can be read with profit and pleasure as a useful and generally reliable guide, it does not give a complete picture of the true incidence and relationship of the various organisms which can cause food poisoning.

A MEDICAL BIBLIOGRAPHY

A Medical Bibliography. A Check-list of Texts Illustrating the History of the Medical Sciences. Originally compiled by the late Fielding H. Garrison, M.D., and now revised, with additions and annotations, by Leslie T. Morton. (Pp. 412. £2 10s.) London: Grafton and Co. 1943.

Mr. Leslie T. Morton, librarian at St. Thomas's Hospital Medical School, has done signal service for all who use medical books by bringing up to date in an independent volume Garrison's remarkable list of historical texts. Thirty years ago the late Dr. Fielding Garrison compiled this list as "a convenient scaffolding" for his now famous *History of Medicine*. But with characteristic modesty he included it in the *Index-Catalogue of the Surgeon-General's Library*, of which he was an official. It has been an unfailing resource to those lucky enough to know it, and it gained slightly wider publicity when he revised it for the *Johns Hopkins Bulletin of the History of Medicine* in 1933. Even so it bore the signs of his wayward genius, and Mr. Morton's edition is a marked improvement in convenience. Garrison's introduction, a thumbnail sketch of his purpose such as only he could write, is missing, but the features repay this loss. First, Mr. Morton's revision has a logical classification and sound indexes, so that the inquirer is not mystified and delayed as he was by Garrison's arrangement. The specialist will find under his subject a neat chronological purview of the outstanding contributions, both books and journal articles. Thus reports on penicillin and sulphamezathine stand at the end of a pedigree deriving from Theophrastus; while Roentgen's paper "On a New Kind of Rays" heads sixteen items on diagnostic roentgenology. Garrison's section of "Original Accounts of Important Operations" was interesting, but each item from it is now properly under its special subject. Then Mr. Morton has added notes to the majority of his entries, much increasing the usefulness of the list. And he has sifted Garrison's compilation and added perhaps a quarter of the 5,500 items, not merely modern references but also filling gaps in the historical material.

Notes on Books

Dr. HOWARD CHARLES BALLENGER'S *Manual of Otolaryngology, Rhinology and Laryngology* was based on the well-established textbook originally written by the late Dr. Lincoln Ballenger. It was intended for students and for those practitioners who need a general survey of the subject. In preparing a second edition for the press (Henry Kimpton; 21s.) Dr. Howard Ballenger has carried out a good deal

of revision, making some changes in arrangement and many additions and amplifications of the text to bring it into line with present-day knowledge and practice. The chapter on paralysis and neurosis of the larynx has been revised and partly rewritten by Dr. John Ballenger. A new chapter, on foreign bodies in the air passage and tracheotomy, describes the technique for tracheotomy, because this is often an emergency measure and as such may be included in undergraduate teaching and in a text for the general practitioner.

The British Association in 1942 formed a committee for the consideration of scientific research on human institutions, with the following terms of reference: "To consider how the results of scientific research on human institutions and human needs at their interrelations can best be co-ordinated and brought to bear on the formation of public policy." The committee's report appeared in the August number of *The Advancement of Science*, and is now obtainable as a pamphlet (6d., or with postage 7d. from the British Association for the Advancement of Science, Burlington House, London, W.1. The main conclusion is that there is urgent need for the setting up of a British Council for the Social Sciences, independent of the Government, with permanent secretary.

The *Handbook of Tuberculosis Schemes in Great Britain and Ireland*, 1943 edition, containing up-to-date particulars of tuberculosis dispensaries, medical officers, institutional accommodation and other details of the tuberculosis schemes of counties and county boroughs, is now available. A list of branches of the National Association for the Prevention of Tuberculosis is also given. Copies may be obtained from the Secretary-General, N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1, price 5s., post free.

Preparations and Appliances

AUDIBLE WARNING OF EMPTY OXYGEN CYLINDER

Dr. MASSEY DAWKINS writes:

Modern anaesthetic apparatus is very nearly foolproof, but there remains the ever-present danger of failure of the oxygen supply. This is particularly the case when working in a darkened theatre, owing to the difficulty of observing the flowmeter. To overcome this a simple piece of apparatus has been devised which gives out a loud warning note when the cylinder is almost empty.

The device consists of a compact unit which can be introduced into the gas tubing conveying oxygen from the cylinder regulators to the flowmeter on a Boyle's anaesthetic apparatus. The attachment is effected by dividing the single common tube which connects both regulators to the flowmeter, and joining the cut ends by the connecting tube of the warning unit. The shut-off pressure of the regulators is usually in the region of

5 lb. per sq. inch, and at this pressure a valve which permits the oxygen to pass through the warning reed remains closed, preventing loss of oxygen, while the supply to the flowmeter is satisfactory. When the pressure falls to a low volume, a spring forces the valve seat off a nipple and the oxygen passes through the reed, causing an audible warning note which indicates the imminent need to change to a fresh cylinder. Then tension of the spring is adjustable to allow the device to operate at any suitable pressure.

The unit works very well in practice and gives a great feeling of safety. It can, of course, be used for nitrous oxide, cyclopropane, etc. The experimental work and the construction of the original model were carried out by Mr. P. A. Toller, L.D.S., of the Royal Dental Hospital, to whom I am greatly indebted. The finished instrument was made for me by Medical and Industrial Equipment, Ltd., of 12, New Cavendish Street, W.1. Thanks are due to Mr. E. Pories for the drawing.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 30 1943

MISREPRESENTATION

Some people appeared to expect that the Annual Representative Meeting last month would be a stormy one, and that, faced with the threat of a whole-time salaried State Medical Service, representatives from different parts of the country would so far forget the patient as to put the doctor first in their discussions. But the meeting, handled with admirable tact by its Chairman, Dr. Peter Macdonald, showed very plainly that it did not come to discuss matters of the highest importance to medicine in a spirit of narrow partisanship. No doubt Dr. G. C. Anderson's address, "Evolution, not Revolution," printed in the *Supplement* of Sept. 4, page 29, had had a sobering effect. The discussions were conducted in a spirit of realism, and with an evident desire among the participants to be constructive in their approach to the problems of medicine in the future. The most noteworthy event of the proceedings was the Presidential speech of Lord Dawson, who put into words of wisdom what are the thoughts and aspirations of that large majority of medical men who see in medicine something more than a means of earning a living.

It was therefore most disturbing to read in the daily and weekly lay press obvious misrepresentations of what had actually been said and resolved. It was clear that propagandists of various views were getting busy and, like some propagandists, were being unscrupulous. The whisper went round, "The B.M.A. is anti-Beveridge"—and in these days it appears that this is the worst one can say of anybody.

So that these misrepresentations may be countered we are printing in this week's *Supplement* a series of statements submitted to, modified and approved by the Representative Body. These give the lie direct to the current accusation that the B.M.A. is "anti-Beveridge." It is as well to recall that Sir William Beveridge said that the problems of organizing a medical service were outside the scope of his report; so he suggested that an investigation should be made into the ways of financing and organizing the medical services. In a leading article earlier this year¹ it was made plain that the B.M.A. offered to co-operate with the Government in achieving the ideal aimed at in Assumption B, but stressed that the report should be acted on as a whole. Not only has the medical profession not set its face against the Beveridge report but it has insisted even more forcibly than many other sections of the community upon the need for securing the individual against the devastating effects on mental and physical health of poverty and of economic insecurity. Perhaps no group of men and women in the community has a more vivid picture than the medical profession of the crippling physical and moral effects of bad housing, insufficient and ill-chosen food, lack of facilities for healthy mental and physical recreation, faulty industrial conditions, and insufficient medical supervision of the man at work and of the

conditions under which he works. Knowing all these things, the medical profession has become highly suspicious of what appeared to be an attempt on the part of the Government to change the structure of medicine instead of getting on first with the job of improving the conditions of life and work of the people. Not only that, but there appears to have been little willingness to attend to those parts of the medical structure which in the opinion of doctors are in urgent need of repair. The B.M.A. is not anti-Beveridge. And Beveridge, we might point out, in looking for a definition of the objects of a medical service, adopted the definition in the Draft Interim Report of the Medical Planning Commission—namely, "(a) to provide a system of medical service directed towards the achievement of positive health, of the prevention of disease, and of the relief of sickness; (b) to render available to every individual all necessary medical services both general and specialized and both domiciliary and institutional."

The majority of doctors are not satisfied with existing medical services, and in fact have expressed their dissatisfaction, and set forth their proposals for reconstruction, now for a number of years. The revised version of the B.M.A.'s scheme for a general medical service for the nation, published in 1938, and the Draft Interim Report of the Medical Planning Commission published in 1942, are witnesses to this. What has been proposed stands there on record. Unfortunately controversy over the Beveridge report—published after the Draft Interim Report of the Planning Commission—has obscured many of the issues; and to some observers not the least part of this obscurity has come from medical men who have seized the opportunity to make these matters an issue of party politics. It seemed, therefore, that an attempt might be made to reach decisions about the future organization of medicine which would be based upon political expediency, and that the really difficult problems of the medical services would not be approached in an atmosphere free from influences which many doctors have come to distrust.

The medical profession is conscious of the need for reform. It has indicated some of the directions in which reform should move. The great majority of the profession believe that experiments should be made before even a working hypothesis is reached. They consider certain matters to be indispensable to the successful treatment of the sick individual. They do not believe that forms of service suitable for the control of environmental medicine and the prosecution of preventive medicine are fitted to individual medicine. They believe that a whole-time salaried State Medical Service would harm the interests of the sick person. They believe, in fact, that the evolution of medical treatment provides the unassailable argument against a whole-time salaried State Medical Service. But this view precludes further developments in the practice of individual medicine. In fact doctors recognize that the whole trend of medical science makes such evolution inevitable. If all these matters are taken into full account in the White Paper soon to be issued, and if the Government is prepared to discuss its proposals with the medical profession in a spirit of true inquiry into the facts and not on the basis of decisions already arrived

¹ *British Medical Journal*, Feb. 18, 1943, p. 193.

at, then we feel sure that in the give-and-take of debate medical men will co-operate whole-heartedly in trying to solve the problem of how to maintain and improve the health of the people.

THE RICKETTSIAE

War and famine are usually accompanied by pestilence, and it will be surprising if the latter fails to play a part in the present world tragedy. Apart from influenza, louse-borne typhus fever probably presents the gravest menace; indeed *Rickettsia prowazeki*, its causative organism, has already given indications of its readiness to take a hand in the game. It is of some importance that we should not allow ourselves to be lulled into a false sense of security by our remarkably good health record to date or by the long freedom from epidemic typhus which this country has enjoyed; we may yet have urgent need of all the knowledge about the rickettsiae which research workers have laboriously acquired. The rickettsiae, as is well known, cause many diseases of both man and animals, apart from louse-borne typhus, and many species are simply harmless intestinal parasites of arthropods—e.g., lice, bugs, mites, ticks, and fleas. The trench fever of the last world war was almost certainly a rickettsial disease; so are Q fever of Australia and Rocky Mountain spotted fever; and it is highly probable that rickettsial agents of many endemic fevers in all quarters of the globe remain to be discovered. By far the most important, however, are the typhus group of fevers, and of these louse-borne typhus holds pride of place because it is the only rickettsial disease, except possibly trench fever, which is primarily a disease of man and hence liable to assume epidemic or even pandemic proportions. Other members of the group, transmitted by mites, ticks, and fleas, have animal reservoirs and tend to remain endemic so far as man is concerned, but there is evidence that flea-borne murine typhus, which has occurred within recent years in Great Britain, may mutate to the classical epidemic form provided that opportunities exist for its transmission through lice. The revelations of Kenneth 'Nanby' concerning the frequency of louse infestations are not without significance in this connexion. It is extremely unlikely that a major epidemic will originate in this country, but conditions in parts of Europe and Asia are becoming ideal for an explosive outbreak, and M. D. Mackenzie² holds the view that widespread movements of population, by introducing the disease into a typhus-free region, may be a factor equal in importance to famine and overcrowding.

There is now little doubt that the rickettsiae are living and reproductive micro-organisms. Akin to the bacteria in some respects and to the viruses in others, they constitute a sort of biological connecting group. They are not filterable in the bacteriological sense, and are visible by ordinary microscopy, especially when stained; moreover, the recent application of electron microscopy to the morphological study of several species has revealed an organized structure within a limiting membrane.³ Like the viruses, however, they have so far eluded all attempts

to cultivate them on lifeless media, and some species appear to be obligate intracellular parasites. Fortunately *R. prowazeki* can be grown in the yolk sac of the chick embryo and in the lungs of infected mice, and both these methods of obtaining large quantities have been applied to the production of vaccines. It is too early yet to say whether the immunity they engender affords satisfactory protection against natural infection. So far only Weil vaccine, prepared from the intestinal contents of infected lice, has yielded satisfactory evidence of efficacy in the field, and this method presents too many difficulties for large-scale vaccine production. The problem of immunization is one of great urgency, for as yet we possess no chemotherapeutic agent capable of influencing the course of the disease; the sulphonamides are quite useless and may actually be harmful.

As regards diagnosis we are on firmer ground. The curious antigenic relationship which exists between rickettsial species of the typhus group and certain strains of *Proteus* has provided a means of easy and rapid laboratory diagnosis. A sporadic case of typhus fever may be impossible to diagnose on clinical grounds, but the Weil-Felix reaction on a sample of the patient's serum, taken towards the end of the first week of illness, will almost certainly give a definite answer. In view of the exceptional importance of the disease at the present time it is far better that the doctor should submit a score of negative sera for laboratory tests than that he should omit to send a single positive one.

INDUSTRIAL HEALTH IN 1942

The Annual Report of the Chief Inspector of Factories contains its usual review on industrial health. It is made by Dr. E. R. A. Merewether, who has succeeded Dr. J. C. Bridge in the office of senior medical inspector. Dr. Bridge succeeded Sir Thomas Legge in 1927, and under his leadership the number of medical inspectors increased to 13. There is little doubt that the prospective growth of medical supervision in industry will entail further increases of staff. As Dr. Merewether points out, the experience of factory life and knowledge of industrial processes clearly indicate the importance of preventive measures in maintaining industrial health, and the success of the measures now in force is suggested by the fact that the health of industrial workers in general, in spite of their arduous labours, shows little sign of regression. Dr. Merewether inclines to the view that mental fatigue, or more properly staleness, is increasing, though it cannot be traced in sickness records; but on the other hand it is encouraging to note that the incidence of certain specific diseases and poisonings is diminishing. This must be due in part to the growing recognition of the importance of adequate diet and the increased provision of canteens, and another factor is the great increase in the number of works medical officers who now total about 850, and of hospital-trained nurses who have risen to about 6,000. One of the most satisfactory improvements relates to dermatitis in filling and explosive factories. A very substantial drop was noted in the number of dermatitis cases due to T.N.T., tetryl, and other explosives, owing to strict supervision of ablutions, the correct application of barrier substances, the gradual elimination of specially susceptible workers, and the mechanization of many processes.

¹ *Med. Officer*, 1941, 65, 39.

² *Proc. roy. Soc. Med.*, 1941, 35, 141.

³ *J. exp. Med.*, 1943, 77, 355.

A novel feature in the report for 1942 relates to the use of radio-active substances, which has so greatly expanded owing to war requirements, chiefly for luminous dials of instruments. Several hundred "luminizers" were examined more than once during the year, but no evidence of a true aplastic anaemia was found. The Factories (Luminizing) Order came into force in May, 1942, and under it various preventive measures, which had for the most part been voluntarily observed for a number of years, became statutory requirements. Furthermore, the hours of work of the luminizers were limited, and workers under the age of 16 were prohibited. Another legal procedure came into force under the Workmen's Compensation Act, 1943, when the provisions of the Act of 1930 relating to workmen suffering from any form of pneumoconiosis were extended so as to include the condition of the lungs known as "dust-reticulation." This condition had been described in detail only a year before in the Medical Research Council report on chronic pulmonary disease in South Wales coal-miners, and its recognition is doubly important as it may result from exposure to the inhalation of dusts other than coal dust. Of the specific diseases and poisonings notified under Section 66 of the Factories Act, lead poisoning in 1942 showed a slight rise on 1941, but the cases of aniline poisoning (mostly due to T.N.T.) decreased from 249 to 204, whilst the cases of toxic jaundice decreased from the 44 (13 fatal) observed in 1941 to 27 (6 fatal). Cases of epitheliomatous ulceration fell from 128 (11 fatal) to 113 (8 fatal), and of chrome ulceration from 103 to 89. The reported cases of gassing showed a slight fall on 1941, the fatal cases being much fewer (25 against 41).

Industrial health is inevitably influenced by hours of employment, and this subject is discussed by Miss F. I. Taylor, a deputy chief inspector. During 1942 the hours worked by young persons were subjected to a detailed inquiry, and to this end inspectors visited all the factories in certain areas in London, Birmingham, Liverpool, Glasgow, and other centres. The average results obtained are more satisfactory than many social workers had supposed, for it appeared that of young persons aged 16 and 17 85% of the males and 89% of the females were working 54 hours a week or less; 56% of the males and 65% of the females were working 50 hours or less; and 48% of the males and 55% of the females were working 48 hours or less. Of the boys and girls aged 14 and 15, 30 and 37% respectively were working 44 hours or less, and the remainder (except for a very small number of illegal cases) for 44 to 48 hours. The inspectors also reported that the tendency during the year was towards a reduction of the hours worked by adult women and men, but no statistics are given.

PHOSPHATIC RENAL CALCULI

The problems presented by phosphatic renal calculi, frequently bilateral, demand the closest co-operation between the biochemist and the clinician. In seeking for the cause of the stones the factors of stasis and infection in the renal pelvis must never be overlooked, however important the underlying metabolic error may be; and when considering their treatment these two factors always need attention, whether or not the metabolism also can be corrected. Since the large branched stones which fill the pelvis and calices are commonly composed of calcium phosphate, often with the admixture of calcium carbonate and ammonium magnesium phosphate, and since they form in alkaline urine, an obvious method of tackling the problem is by dietetic and medicinal measures designed to make the urine acid enough to dissolve the stones. There seems little doubt that the stones vary in their consistency, and the successes

reported by this method have probably been obtained when the stones have been comparatively soft and less compact. The harder stones may still remain undissolved, and call for a more direct method of attack. The operation of nephrolithotomy under these conditions is fraught with so many dangers that any alternative must be carefully considered; and the method of dissolving the stones by instilling solutions of pH as low as 4.0 into the renal pelvis, as described by Suby and Albright, deserves an extensive trial. In their most recent paper¹ on the subject they quote some cases in which the solution was introduced through a nephrostomy wound, while in others no operation was performed but the renal pelvis was irrigated through a ureteric catheter. By such direct approach, of course, the stones may be continually washed over by fluid which is more acid than the urine can be made by diet or drugs. Their earlier attempts to make a solvent resulted in solutions which, though isotonic, were very irritating to the mucosa of the urinary tract; but the discovery that the addition of magnesium ions reduced this irritation led them to adopt a specially prepared solution containing citric acid, magnesium oxide, and sodium carbonate. Even this fluid damages certain bladders, and therefore they devised and now describe in detail an ingenious arrangement whereby intermittent irrigation of the renal pelvis is combined with continuous drainage of the bladder. As the fluid must be introduced through the ureteric catheter every 5 to 10 minutes for several weeks the treatment demands that a nurse shall be constantly in attendance. Even after dissolution of the stone the problem of recurrence has to be faced, but dietetic and drug treatment may be expected to control the reaction of the urine sufficiently to prevent further stone formation. The authors lay stress upon the value of air pyelography for determining whether a stone is in contact with the renal pelvis. They also quote one case in which their method was only partially successful—an outer layer of phosphate was dissolved, leaving the oxalate core unaltered—in order to point out that such stones, unsuitable for this method of treatment, should be recognizable radiographically.

THE PARENT IN THE DOCK

Juvenile delinquency, having reached really menacing proportions, is beginning to stir a faint alarm even in the British public. We received a very ugly shock at the reports—they could not be silenced because they were so many—which came from every country district about the appallingly neglected state of children evacuated from the towns. It has long been a platitude in child guidance clinics that the real problem of a problem child is the parents. Nevertheless, a pamphlet by Dr. L. G. Housden² is probably the first attempt to deal with juvenile delinquencies and other shortcomings from the point of view of the parents, and to assess the extent to which parents are to blame. It is founded on a series of lectures delivered in various parts of England with the object of drawing the attention of the responsible authorities and of the general public to the unnecessarily low standard of child welfare in Great Britain. It is published under the auspices of the National Association of Maternity and Child Welfare Centres and for the Prevention of Infant Mortality. Dr. Housden draws a vivid picture of the "horrible" children of the evacuation, and incidentally of the obscurantist attitude of the authorities. The juvenile delinquents he passes over with bare mention, for he has no need to add anything to our knowledge of that unhappy section. The mismanaged

¹ *New Engl. J. Med.*, 1943, 223, 1.

² *The Parents' Responsibility for their Children*. By Leslie George Housden, M.D. Eyre and Spottiswoode. (3s. 6d.)

child, the victim of the low moral standard of its parents, he studies at greater length, as he does the "ailing children" who are reared on purgatives and quack medicines. The cause of all these ills he regards as our general failure to train parents in child care. This is the cure he advocates, and in doing so he brings much evidence of the success of the attempts that have already been made. He appends a syllabus of courses in mothercraft and home-making (the current alternative to the term "fathercraft").

"THE OPPONENTS OF THE MEDICAL PROFESSION"

This is the heading to the first page of the first *Bulletin* issued by a body which describes itself as "Medical Policy Association (London)." The secretary of this association is Dr. Basil Steele, and the other active members whose names we know of, as they conjointly signed a letter to the Secretary of the B.M.A. earlier this year, are Mr. A. Rugg-Gunn, Mr. Bryan Monahan, and Dr. Russell V. Steele. The aim of this new body is to oppose the introduction of a State Medical Service—a laudable enough aim. It wants to preserve freedom for doctors as individuals: well and good. But it approaches these objects from a theoretical standpoint that will disturb those who wish well of the medical profession. The present situation of the medical profession, the *Bulletin* says, is "essentially a struggle, linked with a general struggle involving the whole of society." It then takes as its text some observations of a Dr. Tudor Jones. According to Dr. Tudor Jones, "The present century has seen the rise into prominence, despite every effort to maintain secrecy and to preserve the appearance of spontaneity, of a vast chain of interlocked organizations, possibly, and indeed probably, inspired from a common source, which pursue a long-term policy." The *Bulletin* lists as "some agents of the general policy": the Fabian Society, the Labour Party, the London School of Economic and Political Science, Political and Economic Planning (PEP). These are the "opponents." The *Bulletin* says that the London School of Economics teaches "strictly orthodox financial tenets, and produces economists who are subsequently employed by the great financial institutions. This fact is the clearest possible evidence of the nature of the threat to society." It all apparently goes to prove the "closest connexion between high finance and Socialism," and the curious complaint is made that those who control the "central financial institutions" are campaigning "to replace control through finance by control through law." The burden of their complaint soon becomes clear in this statement: "The personnel in ultimate control will of course be those at present in control of international finance—the Warburgs, Schiffs, etc." Hasn't something like this been heard before in the eegophonic tones of a broadcaster from a European station? There is an ominously familiar ring about it. In taking a few potshots at PEP our self-appointed medical pamphleteers go out of their way to refer to the position of Mr. Sieff in Zionism. Then they harp once more on the "central connexions" of these movements—that is, the movements of the "vast chain." The "central connexions" are traced to such people as "the Brothers Warburg, Jews who went from Germany to America," Rothschild, Sassoon, Schuster, Schiff, etc.

Fear that these doctors may be introducing anti-Semitism into propaganda for their "medical policy" unfortunately finds support in a subsequent reference in the same *Bulletin* to those well-known forgeries the "Protocols of the Learned Elders of Zion." "There is no doubt that they [the Protocols] are effective plans (i.e., for the complete domination of the world), written with deep understanding

of human psychology," state these would-be discoverers of a world-wide conspiracy. According to a report in an evening paper of an interview with Dr. Basil Steele, Mr. Rugg-Gunn, and two other unnamed medical men, these men said: "We are not against the Jews. We are against Jewish Fascism—international financial control by the Jews." This savours very much of the use of that abominable propaganda device of anti-Semitism to which we have been the painful witnesses in Germany for the last decade, part of something against which Great Britain has been pitting her whole strength for just over four years. We feel strongly that methods such as these are to be deprecated and must, particularly at the present time, tend to injure the cause of the profession.

MORE BACK NUMBERS WANTED

Ten weeks ago we printed an appeal to members who did not preserve the *Journal* for binding to send their copies (preferably in bulk) to B.M.A. House, Tavistock Square, W.C.1, addressed to the Secretary of the Journal Board, who will repay the cost of carriage. The response to this invitation has not been as large as we hoped for, but some members who intend to act upon it may be waiting until they have accumulated a substantial pile of recent *Journal*. There is a constant demand for back numbers from libraries, medical institutions, and other sources at home and abroad, and each issue goes quickly out of print hence any spare copies published during the war will be welcome, both for present purposes and to set aside for the reconstruction of medical and scientific libraries in countries now overrun by the enemy. The steady growth in membership of the B.M.A. to a figure well above 44,000 has increased the circulation of the *Journal* by 14% in the past five years, because every new member must have his weekly copy. Since April, 1940, there have been very severe and progressive cuts in the amount of paper allowed to be used for printing. A member who returns his copies at any time after reading them will by so doing put them back into circulation through the Head Office for the benefit of others, including the newly qualified who are joining the Association in large numbers. The help thus given will be much appreciated in these days of increasing difficulty.

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* have been printed. They will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, B.M.A. House, Tavistock Square, London, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

Sir Henry Bashford has been appointed Medical Adviser to the Treasury. We understand that his duties will be to advise all Departments of the Civil Service on the environmental aspects of health, especially the effect of working conditions on health and fitness. Sir Henry's experience at the Post Office will no doubt enable him to extend to the Civil Service generally the admittedly able system of keeping accurate sick records so long employed by the Post Office, which has made it possible to undertake and publish various long-distance and large-scale observation on industrial health. Sir Henry's task will essentially be that of preventive medicine—the task of keeping the workers well and free from sickness. The Civil Service now has its own doctor, and in appointing Sir Henry Bashford the Treasury could not have made a happier choice.

TWO REPORTS FROM THE R.C.P.

The Royal College of Physicians of London publishes to-day two reports by special committees which are to some extent complementary and should be considered together. The Social and Preventive Medicine Committee was appointed on April 30, 1942, and has met on nine occasions. The Committee on Psychological Medicine was appointed on Oct. 29, 1942, to consider and make recommendations on (1) the training of consultants and others specializing in psychiatry or neurology; (2) conditions of recognition as a consultant in this specialty; (3) the undergraduate curriculum on psychological medicine and related subjects; (4) the future development of psychological medicine. It has met on seven occasions.

Social and Preventive Medicine

The interim report by the committee on this subject is a document of 32 pages, in which are set out the committee's views on the training of medical students and nurses in social and preventive medicine. It also suggests some of the ways in which an appreciation of the conception inherent in that term could improve the services of the medical profession to the community. The changes suggested are in no sense revolutionary; they represent merely a natural growth resulting in a change of emphasis from curative to preventive. To attain the aims outlined in this report the committee makes the following recommendations:

- (i) That every medical school should establish a Department of Social and Preventive Medicine, the size and scope of the department depending upon the facilities and personnel available.
- (ii) That this department should organize a modernized course in social and preventive medicine to replace the present course in public health, which, as in the clinical subjects, should be a curriculum founded securely on the basic sciences, growing and expanding through the three clinical years.
- (iii) That as well as theoretical teaching such a curriculum should bring the student into close touch with the active organizations in the community concerned, particularly with social and preventive medicine—namely, the health services provided by the local authorities, and the almoner's department within the hospital.
- (iv) That all medical schools should recognize the importance of problems associated with industrial medicine.
- (v) That student health services should be available in every medical school, and that under the general direction of the head of the department of social and preventive medicine they should be used as an instrument of teaching.
- (vi) That all teaching hospitals should employ properly trained almoners and psychiatric social workers, both in the care of patients and in the teaching of students.
- (vii) That the Royal College of Physicians should take an active interest in the organization of the teaching of social and preventive medicine, not only to medical students, but also to nurses and medical social workers.

Undergraduate Education in Psychiatry

The interim report of the Committee on Psychological Medicine deals with the subject of the third term of reference only—viz., the undergraduate curriculum on psychological medicine and related subjects. It is issued at this stage with the qualification that it is proposed to embody it later in the full report, and it may need to be modified in detail in the light of the findings of the committee upon the other terms of reference. The interim report is a document of 12 pages and ends with the following ten recommendations:

1. Every teaching medical school should have a department of psychiatry for both out-patients and in-patients, with an adequate teaching staff.
2. There should be a course of normal psychology towards the end of the second pre-clinical year.
3. At the beginning of the student's first clinical year there should be an introductory course on the psychiatric aspects of clinical work.
4. There should be a systematic course on psychiatry extending throughout the clinical period.
5. Six of the lecture-demonstrations of the systematic course on psychiatry should be devoted to mental deficiency, and at least two should be carried out at an institution devoted to the care of mental defectives.

6. Students should act as clinical clerks in the psychiatric department for three months during the first or second clinical year, and should hold a short resident appointment in a mental hospital or observation ward during the last clinical year.

7. The clinician attached to the department of social and preventive medicine should, as supervisor of social studies, work in co-operation with the psychiatric as with other departments.

8. Teaching hospitals should employ more psychiatric social workers.

9. The student's knowledge of normal psychology should be tested by examination at the end of the pre-clinical period.

10. In the final examination there should be a separate examination in psychiatry which might be taken at the end of the clinical period or at an earlier stage.

Pressure on our limited space permits no more than reproduction of the two committees' recommendations at the present moment.

A SURGEON'S LAST MESSAGE

The following letter, headed "Is there Safety in Numbers?" was written by Sir W. I. DE COURCY WHEELER for this Journal on Sept. 11, 1943, the day of his death. It was found in his typewriter and is the last thing he wrote.

SIR,—There is a tendency to-day among some surgeons to claim the right to express dogmatic opinions, and to feel aggrieved if such opinions are criticized, on the grounds that they have dealt with considerable numbers of the cases in question. They claim that they alone are in a position to judge the merits or demerits of the various forms of treatment, and that paucity of material disqualifies all others.

I have been a surgical traveller all my life, and have had priceless opportunities of seeing the great leaders in surgery at work both at home and abroad. The greatest specialists were not those who congregated large numbers of cases of a particular kind under one roof, but those who gave an intense personal study to a few.

Kocher of Berne, as far back as forty years ago, was one of the first Continental surgeons under whom I studied. He worked in a town of 120,000 inhabitants. He was an individualist. Like a painter of portraits he had no place for mass production methods in the realm of surgery. His cases, let us say of fractures, were comparatively few, but each case was treated by himself; possibly each would be seen more than once a day; the slightest deviation from normal alignment was regarded as a crime for which the surgeon was responsible; there was no delegation of duties to others. Kocher's entire time was spent in dealing with a few.

Can there be any question as to which is the greater authority, the surgeon who nominally has under his care a hoard of patients, to each of whom he can personally give but the scantiest attention, or the surgeon who has spent an equal amount of time studying intensively a few? The incentive to obtain results above reproach is greater when a few cases are in question than when large numbers form a queue. In the one case there results the well-finished hand-made article of the craftsman, in the other the less reliable output of mass production.

RESTORING THE INJURED MINER

The Miners' Welfare Commission has issued a useful four-page leaflet entitled "Rehabilitation Treatment for Injured Coal Miners," which actually covers more ground than this title suggests, going back to the time of the injury and explaining how the best medical care can be obtained. The accident rate in mines, it states, is six times as high as it is in factories, and the injuries are often very severe. When an accident occurs the colliery management or the colliery doctor must decide where the injured man should be sent for treatment, and much depends on a wise decision at this stage. Cases of fracture of the arm, spine, or the lower limbs from the pelvis to the foot should be sent immediately after first-aid treatment to a hospital with an orthopaedic or fracture department. These departments have been established in both England and Scotland at selected E.M.S. hospitals, the names of which can be obtained from the local representatives of the Ministry of Fuel and the Miners' Welfare Commission. The leaflet points out that every doctor and colliery ambulance man should know which hospital having such a department serves the area of the colliery. The cost of treatment, whether the fracture occurs during work or not, is borne by the

Ministry of Health or Department of Health for Scotland so far as it is not defrayed by the patients through contributory schemes or otherwise.

Rehabilitation, which is described as "the rounding off of good hospital treatment," can be provided, the leaflet continues, in almost 80% of cases at out-patient departments. For the remaining 20% rehabilitation at a special residential centre is necessary, and two such centres are already functioning well. Berry Hill, Mansfield, was taken over by the Miners' Welfare Commission at the beginning of the year, and the centre at the former Gleneagles Hotel was opened last January. Further centres, linked with the fracture service, are being developed by the Miners' Welfare Commission, to serve all the major coalfields. There is no charge for treatment at these special centres and patients' travelling expenses are repaid. The centres have no connexion with workmen's compensation and no reports are made for compensation purposes. Patients are recommended for admission by the surgeon responsible for treatment in hospital, or, in old cases, by the panel or colliery doctor, but the surgeon at the centre alone is responsible for deciding whether the patient's injury is suitable for treatment at the centre. The leaflet adds that an important factor aiding the speedy recovery of injured miners is the assurance that they will be re-employed afterwards. As the patient is not discharged until he is fit to start work there should be no interval when he is unemployed. At Mansfield 95% of 400 consecutive patients who had had long periods of total incapacity have been reinstated in industry. For the few who are prevented by some permanent disability from returning to the mining industry training is provided under the Interim Scheme of the Ministry of Labour for the Training and Resettlement of Disabled Persons.

REHABILITATION CENTRE FOR DOCK WORKERS

It has taken an acute shortage of man-power during the war to focus attention on the fact that the restoration to health of the sick and injured dock labourer in an island country is a matter of national concern. The explanation apparently is that hitherto the casual nature of the work has made organized rehabilitation among the men impossible. Now, however, with the registration of all dock workers the follow-up of those who are absent through sickness is made easier, and the authorities for the area of the port of Manchester have taken the next logical step and established a rehabilitation centre at Salford, where dock workers may go for advice and treatment. The centre is in an old mansion—Claremont, Eccles Old Road, Salford—which had been developed as a hostel and welfare centre for transferred dock labourers, and which, with its extensive out-buildings, has been equipped to provide physiotherapy, gymnastic, and social departments. The whole is administered by a committee, upon which, among others, are Dr. A. E. Quine and Dr. J. M. Ross, representing the Ministry of Health, and Dr. Joan Harwood of the factory inspectorate. The medical officer in executive charge of the centre is Dr. J. P. Broom, who was appointed last year and who has been supervising the lay-out and equipment and making himself familiar with the technique used in other rehabilitation centres throughout the country. He will have the help of a welfare officer of the Ministry of Labour, and the individual records of the men on the dockers' register and other facilities will enable him to get into touch with those to whom the centre may be of service. While Dr. Broom will advise an injured man on the special treatment suitable to his particular needs, he will do so without interfering in any way with the existing relationship between the man and his own doctor. The advice and treatment will help in large measure to check the tendency to return to work too early, but a much more telling factor will be the subsistence allowances that are to be made while earning capacity is reduced. These allowances amount to as much as 55s. a week (less sick benefit, pensions, etc.) in the case of the totally unfit worker, while there are suitable payments for the partially fit, who attend at the centre on certain days or for part of a week only. In addition, a midday meal is to be provided free of charge for those attending all day, and travelling expenses are to be refunded. Care is to be taken to see whether the dock worker is able to resume his former occupation or whether a transfer to a different type of work would be more beneficial. The centre is already in operation, and should be able to deal with 50 patients when it is fully functioning.

The increase in the number of women doctors in Germany in 1943 (*Koeln. Ztg.*, May 7, 1943) amounts to about 40% compared with 1939. This corresponds to the increase between 1937 and 1939. In the next two years still greater increase is expected. At present there are 9,426 women doctors in Germany in a total of 73,960 doctors. Of these women, 5,146 are in salaried employment, 2,210 have taken practices, and 2,070 are not employed in any medical activity: 74.7% of them are married and 47.1% of them are married to doctors. With the incorporation of the Ostmark, the Sudeten territory, and the Ostgebiete, 1,200 women doctors were brought into the Reich.

Reports of Societies

THE CRIMINAL, THE PSYCHIATRIST, AND THE STATE

The presidential address to the Section of Psychiatry of the Royal Society of Medicine was delivered on Oct. 12 Dr. W. NORWOOD EAST, formerly H.M. Commissioner Prisons, who discussed the subject of psychiatry in relation to the criminal.

Although there was no justification, he said, for the belief that crime *per se* was an indication of mental disorder, repeated criminal behaviour by the same offender might be the result of mental abnormality. The Home Office classification divided crimes into six main groups, which were not mutually exclusive: offences against the person, offences against property with and without violence, malicious damage, forgery, offences against currency, and other offences; but this classification lacked significance for the psychiatrist because legal and official approaches differed from scientific approach. The legal interest in a killing, for example, might depend upon differentiation of murder from manslaughter, while the medical interest was chiefly concerned with the personality of the offender. For medical purposes crimes could be classified as acquisitive, aggressive, sexual, gregarious, and the like, according to the instinct involved. These classes were incompletely differentiated. The crime of "entering" might relate to the acquisitive, the sexual group. Some cases of murder or arson were primarily sexual and associated with the aggressive.

After some comments

the State to the scientist might be less effective in crime and the role of that doctors

groups, as were usually was no peddled in criminology medical qualifications ready to make of the persons years exception; evidence given in the opinion of accused. He referred to psychologists seem views were likely to

Dr. East believed the mental condition of a psychological function. who were registered in men who had no special eminent they might be in, steadfastly refuse to be a witness box concerning the in the association of mental

Functions of Justice

The protection of society from the criminal, the psychiatrist, the latter was in favour of the criminal; this was the training of the physician led him to consider the patient before other considerations. the wider interests of society must be in favour of the offender. Any such attempt to injure him as well as the society in which he lives, on the other hand, it was very important that the psychiatrist should be maintained; his opinions must not become subservient to the law of the moment. Dr. East believed it to be a mischievous suggestion that the mental condition of a person should be decided by a medical referee, the president of the

determine the issue. If the results of a psychiatric examination were to be informed and purposive the accused must feel that the medical examiner was able to extend to him a hand of human sympathy and understanding. If the medical referee had merely to assess the value of the documentary evidence and the opinions of the expert witnesses without himself making a personal examination of the offender, he would often find himself uncertain and dissatisfied and sometimes wrong. But it was quite impossible to carry out a psychiatric examination satisfactorily in court: it required the most favourable conditions available, and immediate contact with the accused. Less objection would seem to apply to a procedure which restricted the duty of the jury to finding the prisoner guilty or not guilty of the crime, leaving the question of insanity and irresponsibility to a medical tribunal before the court determined the sentence.

But nowhere did there seem to be any willingness to transfer the functions of the court and jury to the psychiatrists, and he did not believe that the psychiatrists wished this duty to be imposed upon them. Their training and experience were not necessarily the best to apply to wider issues, and they might be able as psychiatrists to carry a case only partially forward to the final conclusion. Different interpretations of the significance of the same set of facts might be made by warring expert witnesses, and an intolerable burden would be placed upon psychiatry in its adolescence if it had the last word in a criminal court. For example, a sexual perversion might be the result of a constitutional anomaly, but was the psychiatrist the person to decide whether its overt expression should be more tolerated than that of sexual offences which were not due to perversion and which might be more urgent than the less forceful drives of many perverts?

Criminal responsibility was a legal concept which the public understood and of which it approved, and so far psychiatry had not replaced it by anything more precise or practical. Criminal responsibility and the culpability recognized by medical men should be regarded as two different things. If the former were left to the lawyers there would be more time to study closely the medical conception of culpability, for this was likely to become increasingly important with the crystallization of knowledge concerning minor mental abnormalities.

Psychological Treatment of Crime

The psychological treatment of crime was so recent that its scope was still uncertain. It was not to be recommended lightly or without discrimination, and it might be expected for some time to come that unsuitable cases would be suggested for treatment as well as suitable ones. The study of minor mental disorders, as well as the introduction of new methods of treatment, had opened up new possibilities in the scientific attack on crime. But a psychological investigation, while it might explain conduct, did not necessarily excuse it. There was a growing tendency in the courts to consider the criminal more than the crime, but the welfare of the criminal must often be subordinated to the wider interests of society. Imprisonment might be necessary for public reasons in spite of the fact that non-custodial measures had been recommended by the psychiatrist. Conversely, detention over a prolonged period, with or without special psychiatric and rehabilitative treatment, might be desirable from the medical aspect but not justified by the nature and circumstances of the crime.

Perhaps the most outstanding feature of the association of the modern psychiatrist and the criminal was the recognition of the importance of the emotional genesis of crime. The study of sexual crime, in particular, had contributed much in recent years to a better understanding of instinctive action when directed towards criminal purposes.

After discussing some of the proposals put forward in the Criminal Justice Bill, 1938, which was being considered at the outbreak of war, and the intention of which was to grapple still more closely, individually, and efficiently with the ever-present dilemma of penal reform, Dr. East concluded with the remark that in his judgment some of the intricate problems involved in the scientific approach to crime and the scientific treatment of mentally abnormal criminals belonged to the borderland between mental disease and anomalies of character rather than to the territory dividing mental health from mental illness. However this might be, the psychiatrist's part must

be carried out in the spirit of the scientist who was able to take the long view, willing to serve both State and lawbreaker, and, in spite of disappointments and rebuffs, a firm believer in man's usefulness to man.

A hearty vote of thanks was accorded to Dr. East on the proposition of Dr. Hubert J. Norman, seconded by Dr. J. Brander.

Correspondence

Old Lamps for New

SIR.—In a recent article in the *Guy's Hospital Gazette* Brig. W. H. Ogilvie, in speaking of wounds in the East African campaign, makes the following statement: "Drainage should be by gauze impregnated with some oily medium. Vaseline has proved its worth in many fields and in thousands of cases." Here we have a return, literally, to one of the household remedies of our grandmothers for the wounds of the greatest war in history.

Again, in your issue of March 20 last and in your leading article "Rehabilitation of the Flavines" you merely state what many of us—simple souls, no doubt—have found by experience during the last 20 years to be the best antiseptic for routine use in general practice. Does it not seem a matter for regret that while so much lip service is paid to the general practitioner, and his potential value in clinical research emphasized, his views are never really canvassed on any medical subject?—and herein lies the weakness of much medical research.

The present tendency towards extreme simplicity in the treatment of burns—reliance being placed chiefly on sulphanilamide in petroleum jelly or on sterile petroleum jelly alone—only tends to support the use for many years of acriflavine emulsion with its conspicuously successful results, though this preparation is belittled in your article. Such disparagement, no doubt, is comparable with the successful clinical use of strychnine in cardiac cases and *lotio plumbi cum opio* as an anodyne, though both have been condemned experimentally as of very little use. We thus see in the course of four years a complete swing over in the treatment of burns, from an attempt to convert a case of burns into the commonly accepted picture of an Ancient Briton to a few simple dressings of petroleum jelly.

What, then, is wrong with medical research that it has (in spite of some great forward moves) to scrap so much that has at one time seemed almost fundamental in therapeutics—e.g., tannic acid and the aniline dyes in the treatment of burns? Some problems are befogged by over-simplification, others by over-elaboration. Medical research seems to be hindered by the latter. Masses of facts are collected and presented in columns and tables at different times. Does anyone ever attempt to correlate all these hieroglyphics which are served up to us, or do they merely remain as disjointed monuments to the industry of the collectors? There seems to be an incurable fondness for this heaping up of Pelion on Ossa and Ossa on Olympus of facts based on experimentation and not on clinical observation of the human being. A few years before his death Lord Moynihan said there was ample clinical opportunity for research, though later he seems to have recanted and bowed to orthodox opinion.

These reflections may be mere presumption in a general practitioner and, like the Psalmist, he should perhaps say, "These things are too high for me." But again, like Rosa Dattle, "I merely want to know."—I am, etc.,

Hove.

G. L. DAVIES.

Early Recognition of Cancer

SIR.—Your correspondent Dr. Joseph Walter (Oct. 16, p. 493) states that the new Cancer Act will mean a great step forward in the treatment of cancer, and he urges that talks on the wireless and at the pictures and by lectures, advertisements in the Press and, presumably, on all the hoardings and buildings, the distribution of popular booklets on the recognizable symptoms of cancer in various organs will in the earlier recognition of the malady. How much is true?

I cannot help but feel that in those sites where the lesion is capable of early detection the patient suspects the nature, and because of a knowledge of the outcome of similar lesions in his friends tried to escape by secreting the evidence, hoping against hope that the suspicions will prove to be unfounded. I do not believe that the average person is so stupid as to ignore such lesions, for medical men and members of their families do not appear to come forward any more quickly than laymen; in fact the former frequently come for examination in the first instance because of the insistence of the non-medical relation. Your correspondent says pessimism about cancer is out of date. Was pessimism with a patient, whatever the condition, ever in date? The cancer expert who says to the patient: "You know what is the matter with you, missus; you've got a cancer," is not out of date but, so long as he cannot provide a certain cure, is inexcusably brutal.

The personal experiences given in your columns in the letters of William Gorse and Percy Furnival must have left some impressions: the latter "formed the opinion that the treatment he had undergone had increased his sufferings and made his passage more difficult, and he wished in his love for humanity to save others from a like fate." All of the cancer clinics could provide similar cases. So much for the cancer which can be recognized in its early stages. There are others which the patient suspects and the most exhaustive investigation fails to discover, even after the development of obvious secondary metastases. In some cases recognition of the primary is impossible at the post-mortem examination.

In the period of 1931 Paris and its environs was disfigured by huge posters about cancer, and at that time their Radium Institute was a model possessing the most up-to-date scientific equipment for cancer research. Has the incidence or mortality of cancer been reduced in that city or in the cities of this country where for years cancer teams have been energetically working? I can see no difference in the cancer rates in this country between those cities with the clinics and those without, and therefore I can see no reason to multiply such clinics if they are merely to repeat the work which has really not brought us any nearer to the solution of the problem. In such clinics there is a tendency in treatment to neglect the patient, not only in the clinical examination but in the response to treatment, and to rely on investigations in ancillary departments and data provided by the physicist. No matter how accurate the latter, the very variable factor of the patient cannot be estimated; for some years treatment was based on a fictitious "lethal carcinoma dose" of radiation because the patient factor was overlooked. With regard to the former, I wonder, for instance, how often is there failure to carry out a digital examination of the rectum where a radiological investigation is readily available. I have known the former to be neglected when the patient has complained of bleeding, pain, and a feeling of fullness in the rectum, when a secondary haemorrhage has been found and recognized histologically, and when parotomies and hysterectomies have failed to reveal the primary, which was within 2 in. of the anus. On the other hand, there is the question of the cancer expert and his ability to appreciate early signs. I have known definite radiographic signs to be neglected for months until clinical signs were recognizable.

Would it not be better to have two or three institutes investigating different aspects of the problem rather than multiple duplications of the present activities, and, in particular, a more careful investigation of the factors which bring cure to the small proportion rather than a prolongation of an existence to a larger number? The best and most attractive advertisement for cancer patients will be the announcement of a certain cure. I believe they know the early signs as well as we do and will not wish to have the bogey intruded before their minds when they seek recreation.—I am, etc.,

Birmingham.

JAMES F. BRAILSFORD.

Statistics of Neurotic States

SIR.—I was interested in Dr. Howard Collier's article (Oct. 9, p. 461) on the statistics of neurotic states in cases sent to medical referees. Some of his figures, however, require considerable study. He begins by explaining that a total of 2,000 cases were examined for the study, yet only 1,693 cases appear in the statistical table. It is not clearly explained where the

discrepancy arose. In the interpretations of the results to statements are open to criticism. The conclusion that about 280 per 1,000 of all cases of unduly prolonged disablement are due to or associated with manifest nervous or psychiatric disease is acceptable, but if that is the case, it is not true that 280 in every 1,000 disabled persons are likely to experience an unduly prolonged disablement by reason of "nervous disorders." According to the figures, there were out of 100,000 people at risk about 66,000 claiming benefit each year—1 in 3. With an estimated total of 770 to 1,540 neurotic cases showing prolonged disablement, this obviously gives rate of well under 280 in every 1,000—only 12 to 24 per 1,000 in fact.

Lower in the article a correct rate of 3.8 is calculated representing the number of cases per 1,000 showing prolonged disablement due to neurosis during the year 1940. Strange enough this rate is stated without any time limit, implying that it is the number showing neurosis at any time. That this is a real error of judgment is shown by the next statement that since 1 in 3 persons claims benefit each year the rate per year is 1.2 per 1,000. This argument will not bear scrutiny and the statement is meaningless, since the yearly rate has already been calculated, being a minimum of 3.8 per 1,000. The rate of cases at any time, implied in the rate of 1.5 per 1,000 requiring "expert psychiatric help," cannot be calculated without knowing the average duration of a psychiatric case, a subject worthy of considerable discussion. The figures produced are estimated totals for a quite arbitrary period of one year (1940).

Since this statistical method may well prove in post-war years to be a valuable method of acquiring information, one in which the average doctor may have to interest himself willy-nilly, it is of extreme importance that the aims and limitations of such a method should be clearly kept in mind. It would be an additional advantage if statistics could be presented in such a way as to be easily followed by an ordinary person like myself. Even at the expense of over-caution or over-simplification, it may be worth while trying to avoid the oft-repeated dictum that "statistics can be made to prove anything," a statement which often follows on a statistical survey that is difficult to understand and check.—I am, etc.,

Hamilton.

E. A. TURNER.

Mind and Stomach

SIR.—Was it by chance or design that you published in your issue of Oct. 16 Sir Henry Tidy's outstanding communication "Peptic Ulcer and Dyspepsia in the Army" and in your leader dealt with Masserman's recent work on behaviour and neurosis? One cannot help feeling that the increase in dyspepsia, organic and non-organic, among the civilian population during the past two decades, and also increased incidence in the Army during the present war, might be explained by a further study along the lines suggested in Masserman's book. The past twenty years have been years of tension, anxiety and insecurity, which might well be a disturbing factor in the total apperceptive field. It would be interesting to hear the views of the writer of your leader.—I am, etc.,

London, W.1.

LEOPOLD MANDEL.

Treatment of Septic Hands and Fingers

SIR.—As one of the many "most junior house-surgeons" sole charge of septic cases, I cannot let Dr. E. C. Atkinson's letter (Oct. 2, p. 432) pass unchallenged. We haven't a trade union to challenge him, although his plea for "standardization of propaganda" might suggest we have. The following remarks are presented in all humility, as an impression—not a statistical survey—after two months' work in a busy casualty department.

"The supervision of the ripening stage" intrigues me. As I see only 5% of septic hands in the stage of invasion ("ripening stage" is rather pickle bottle!), Dr. Atkinson is indeed a lucky man to be able to use such an expression. When seen 95% are either in the stage of localization or in the stage of neglect (in my own nomenclature) and require immediate incision. In fact patients arrive days after they should have come. Two people are to blame for this. First, the patient who "won't give in," this is particularly common in Service patients on leave. Second, the doctor who often foment the infection for days (14 days in a pulp infection being the record) and then sends a letter to the

"considers it now fit for opening and drainage." Yes, one iter said "and drainage"! Also the childlike faith in chemotherapy delays arrival at hospital and the attention of "the most minor house-surgeon."

Let me quote: "I shall be grateful if you will open this man's ind, which has not cleared up in spite of sulphamylamide"—he might add also in spite of inadequate dosage of 2 g. day (none a night) for four days. This is an opportune moment to remark that, as so many cases are only seen in the stage of realization, Dr. Atkinson's "no doubt in the future penicillin will vanish the boggy of the septic finger" seems unduly optimistic. In fact we may surmise that, when the fairy godmother who produced chemotherapy (in spite of which infection occurs!) gives forth penicillin bountifully, septic hands will reach "the most minor house-surgeon" in even greater stages of decay.

Next I should like to assure Dr. Atkinson that incisions are ever hurried. Fingers are opened with ring-block anaesthesia. I have done 100 now, of which 40 were infected—e.g., cases of aronychia and pulp space infection. In not one single case as there been any complication whatsoever, despite the frequent criticisms one hears. The remaining infections are opened under O_2 -and-oxygen in the same leisurely manner. Students work under observation, equally conscious of their responsibility in treating a worker's hand.

Dr. Atkinson continues, "The results of this surgical team work can be seen in large numbers every day in out-patient departments, where the patients attend for hot soaks, probing, and re-incision." Hot soaks are taboo except in the stage of invasion. With an open wound they make the tissues boggy and encourage mixed infection; and it is quite illogical to expect to hasten the process of elimination by washing the surface of a slough with hypertonic saline for half an hour a day. It has not been necessary to use a probe on any occasion. Only two cases have been re-incised. One was a foreigner with a subcuticular whitlow. The patient complained of so much pain that one was fooled into incising as a pulp infection. The other was a paronychia where a fungus infection was missed.

Dr. Atkinson is indeed unfortunate if he sees the cases he mentions "in large numbers." There have been three cases of osteitis, in each case as a result of a pulp infection the diaphysis sloughed. They were seen after 10, 12, and 14 days respectively. Two of these had been poulticed for that time by their doctors.

Despite what Dr. Atkinson says it is not the young generation who make the mistakes in treating hands. It is the older practitioners who are so often guilty of complacency. He will be also startled to learn that students have no idea of the after-treatment of gastrectomies and lobectomies but get several excellent lectures on hands. Old beliefs die hard. Only the other day, on the subject of vaccines for boils on the neck, one of the very aetiological factors was recommended, thus: "Vaccines! No! The best treatment is a damn good bread poultice. That was good enough in my time."

May I conclude with four observations. (1) No doctor should go into general practice without having done a casualty job. (2) Consider the patient as well as his hand. He has to knock off work, he hasn't slept for several nights, and if ever an individual needed encouragement it is the man with the infected hand. The strongest men often arrive on the verge of tears. Incision and medial provide a good night's sleep which quickly restores confidence. (3) No finger should ever be seen in any position but the position of function. A straight finger should be a crime. (4) Lastly, none should start to treat hands without having absorbed Marc Ibelin's *Surgery of the Hand*.

The worst mistakes are not made by "the most junior house-surgeons," but by the Dr. Blimps—amid shouts of, "Arrogant young puppy!"—I am, etc.,

Croydon General Hospital.

CHARLES ROMER.

SIR,—Attention is called by Dr. E. C. Atkinson (Oct. 2, p. 432) to the need for official advice to medical men throughout the country on the treatment of injuries and infections of the hands and fingers. Nearly a year ago (Dec. 12, 1942, p. 706) I made a similar plea: I hope Dr. Atkinson's appeal may meet with more response.

I am in entire agreement with all Dr. Atkinson's remarks and suggestions, although I feel that, in view of the importance of the subject, it would be better if the memorandum were drawn up by the Medical Research Council. A few days ago it was announced in the B.B.C. news that during the last year there has been a great increase in industrial accidents. When it is considered that 50% of these accidents involve the hands and fingers, and that the resulting disability is due, more often

than not, to maltreatment, the need is clear for an organized endeavour to improve the present deplorable standard of treatment of these lesions.—I am, etc.,

J. B. OLDHAM,
Surgeon-Commander, R.N.V.R.

Emergency Treatment of Fractured Femur

SIR,—In the *Journal* of Sept. 11 a description is given by Major P. L. Williams, F.R.C.S.Ed., for the emergency treatment of fractured femur with only a stretcher and triangular bandages or straps. During the last war we used the following method with great success:

The patient is laid on the stretcher, a clove hitch is put round the boot of the injured limb and tied firmly to the handle (it is as well to put on two clove hitches as it is most important that this fastening should be firm). Two triangular narrow fold bandages or straps are put under his axillae and made ready to tie to the handles of the stretcher at the head end.

The stretcher is now upended—i.e., the feet are raised right up so that the patient is almost standing on his head: the weight of the body extends the limb fully, the bandages (or straps)

under the axillae are then fastened firmly to the stretcher handles, and the stretcher is lowered. The limbs can now be tied together and a strap or straps put right round the stretcher and limbs. The effect of this is that the limb is fully extended and the ends of the broken bone are separated, the side of the stretcher acts as a splint, and the whole limb is firmly fixed and will stay in position, and the patient can travel in comfort.

The whole operation is extremely simple, can be done in a few minutes, and is very easy to teach. This method can be used for any fracture of the lower limb above the ankle, and if it were generally known would save infinite pain and suffering. I enclose three sketches which illustrate the method.—I am, etc.,

G. D. LANG,
Limpfield, Surrey.

G. D. LANG,
Late Temporary Major, R.A.M.C.

Significance of the Rh Factor

SIR,—It is apparent from several recent articles that the significance of the relationship of the Rh factor in paternal and maternal blood is becoming generally appreciated. The influence of this factor on the health of the offspring of an ill-matched couple is of particular importance. The chances of a child in such a family being born in good health are considered by Race and his co-workers in your issue of Sept. 4, 1943, and the results are not encouraging.

According to the iso-immunization theory (Levine *et al.*) the children of a homozygous Rh-positive father (RhRh) and an Rh-negative mother will almost always show manifestations of

Miss Jean M. Dollar (Royal Eye Hospital). An investigation into the value of cockerel serum in ophthalmic surgery, with especial reference to its use in connexion with mucosal and corneal grafts.

Miss Shirley M. Draycott (Royal College of Surgeons). The effect of the administration of sulphhydryl amino-acids on the anti-syphilitic action of arsphenamides.

It was reported that the Blane Medal had been awarded to Surg. Cmdr. D. P. Gurd, R.N., for his thesis entitled "An Investigation into the Incidence of Trachoma in the Maltese Islands."

A Diploma of Fellowship was granted to F. H. Masina and Diplomas of Membership were granted to C. O. Fung-Kee-Fung, R. N. G. Holloway, L. Howell, P. H. Huggill, J. A. Loveless, R. G. May, A. D. Payne, M. I. Pott, N. H. Seaton, and B. A. Ward.

A Licence in Dental Surgery was granted to A. C. Horne.

Diplomas in Child Health were granted, jointly with the Royal College of Physicians, as follows:

Patience E. Barclay, Monica M. Bird, J. P. Bound, Annie E. Burns, Cecil M. Driffield, Margaret Egan, H. V. L. Finlay, Cecilia Henry, L. Hornung, Margaret M. P. Jolly, F. L. King Lewis, F. G. Leslie, Kathleen B. McClintock, Rosaleen De C. McCormick, Mary H. McC. Snape, Cecilia V. Urquhart, Fanny D. Wride, H. J. Young.

The Services

Prob. Temp. Surg. Lieut. M. J. Hood, R.N.V.R., has been awarded the D.S.C. for courage, endurance, and great skill in tending the wounded when H.M.S. *Achates* was lost.

The following appointments, awards, and mentions in recognition of gallant and distinguished services in the Middle East have been announced in the *London Gazette*:

C.B. (Military Division).—Brig. K. MacCormick, C.B.E., D.S.O., C.H.S., New Zealand Military Forces.

C.B.E. (Military Division).—Brig. (local) W. D. D. Small, R.A.M.C.

O.B.E. (Military Division).—Majors (Temp. Lieut.-Cols.) D. M. Blair, R. H. Bland, E. Bulmer, J. B. S. Guy, T. D. Phelan, and J. C. Verbi, R.A.M.C.; Major A. L. Chute, R.A.M.C. (attached R.A.M.C.); H. W. Farrell, J. Morgan, I.M.S.

M.B.E. (Military Division).—Major P. J. May, Capt. (Temp. Majors) A. K. Borland, D. MacL. Douglas, M. H. Evans, C. P. Stevens, and J. C. Summ, R.A.M.C.; Capt. H. C. Allan, K. G. A. Arlow, A. M. Lester, G. B. Northcroft, K. R. D. Porter, and A. F. Smith (deceased), R.A.M.C.

D.S.O.—Majors (Temp. Lieut.-Cols.) L. T. Furnivall and R. McIlrion, D.F.C., R.A.M.C.

M.C.—Capt. R. G. MacLeod, A. D. Parsons, M. J. Pleydell, W. Taylor, and C. W. Warner, R.A.M.C.

Mentioned in Despatches.—Capt. (Temp. Majors) R. W. Cope and G. M. Willoughby, R.A.M.C.

The following appointments and mentions in recognition of gallant and distinguished services in Malta have been announced in the *London Gazette*:

C.B.E. (Military Division).—Col. F. Whalley, D.S.O., T.D., H.P., late R.A.M.C.

M.B.E. (Military Division).—Capt. (Temp. Major) H. G. Gernstein, R.A.M.C.

Mentioned in Despatches.—Capt. (Temp. Major) (Acting Lieut.-Col.) C. J. Cellan-Jones, Capt. (Temp. Major) W. O. MacFeat, Capt. C. V. Light and R. Mitchell, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Surg. Lieut.-Cmdr. D. J. WILKES, R.N.V.R., was killed in action recently by a bomb splinter and buried at sea. He began his education at the Old Edgbaston School and later at Birmingham University. He acted as house-surgeon at the General Hospital, and afterwards joined his brother-in-law, Dr. Dennis Allin, in practice in Birmingham. He volunteered for the Royal Navy and was called up at the outbreak of war. He took part in the Lofoten raid, the Dieppe raid, the Algiers raid, and finally Sicily. Tributes to him were received from the captains of the ships in which he had served. Officers and men alike wrote and mourned his loss. One tribute was from the Commander-in-Chief of the station in the Mediterranean, who wrote to his captain: "It was a most unfortunate and sad thing that you should have lost Wilkes at a time when he was badly needed, and the more so when he had given such good service and his relief was on the way. A man of such sterling character and so many excellent qualities will be sorely missed. We cannot afford to lose such as he."

Killed.—Capt. J. O. D. Williams, R.A.M.C.

DEATHS IN THE SERVICES

To many retired R.A.M.C. and I.M.S. officers who had served in India and Burma the news of the sudden death on Sept. 16 of Capt. T. HENDERSON BROOKS, I.M.D., will come as a shock. In his 33 years of service in the various large station hospitals in India he had come to be recognized as a very efficient organizer and administrator in hospital matters. A correspondent writes: His genial, jovial personality, sincere

and humble ways, and his ever-ready willingness to help and to advise, earned for him the respect and affection of officers and men alike. Born in 1872 in Karachi, son of one of the earliest settlers in the Province of Sind, he entered the military medical service in 1894. Till 1897 he was employed on platoon duty in the Bombay Presidency, receiving the personal thanks of the Governor for his services. In 1898 he received a Tirah campaign medal with clasp—actually helping P. Findlater when the latter gained the V.C. From 1901 to 1905 he was in Burma to deal with the very severe plague epidemic prevailing there. His elder son contracted the disease but survived. Once again for his services he earned the commendation of the Governor and the public. He was specially chosen in 1912 to accompany the Hkhomeptilon Expedition to the frontiers of Burma and China. Returning to military duty in 1916, he saw service with the 19th Indian General Hospital Salonika. After his return to India in 1919 he became personal assistant to the A.D.M.S. on the Raymak Expedition 1921-2. Besides the medal he was mentioned in dispatch and received special promotion. On retirement from military service Capt. Brooks settled in Karachi and continued to keep alive the reputation and skill of the family in the Province physicians—a reputation established by his father and handed down to each brother in turn (for there were several brothers as doctors) for a period of nearly a hundred years. He left a widow and two sons: one is serving in the Indian Army in the Middle East and one practising in Gloucestershire.

Fl. Lieut. JOHN KENNETH DENHAM died on May 9 while on active service, aged 37. He studied medicine at Cambridge and St. Thomas's Hospital and qualified M.B., B.Ch. M.R.C.S., L.R.C.P. in 1938. After holding house appointments at St. Thomas's, the Brompton Hospital, and the West (L.C.C.) Hospital, Fulham, he was appointed to a commission in the Medical Branch, R.A.F.V.R., on June 13, 1943. At the date of his death he was medical officer to a squadron operating over-seas.

Medical Notes in Parliament

Regulation 33B

Mr. ERNEST BROWN, in reply on Oct. 14 to Mr. GRAHAM WHITE, said that Regulation 33B was substantially helping local authorities to get into touch with persons suffering from venereal disease and to induce them to undertake treatment. Up to June 30 last 1,893 cases were brought to the notice of medical officers of health in this way. The number of cases reported more than once as alleged sources of infection was 110. In 3 cases it was necessary to take proceedings for failure to carry out treatment. Dr. SUMMERSKILL commented that on six men had been reported under Regulation 33B. Mr. BROWN said the Regulation was making a very useful contribution to reducing the incidence of venereal disease. Sir A. BEAVER asked whether the majority of the 1,800 cases were persons who had been compulsorily examined. Mr. BROWN said they were cases brought to the notice of medical officers.

Hetherington Committee's Report

Mr. JOHNSTON said on Oct. 13 that he had that day received the report of the Hetherington Committee on the Reorganization of Scottish Hospitals. The report contained many important recommendations affecting the future of the hospital system of Scotland. Those recommendations were being considered in connexion with the Government's examination of the whole question of a new national health service.

Physical Fitness for Employment

Mr. RHYS DAVIES asked on Oct. 14 whether Mr. Bevin knew of the growing practice of employers to engage medical officers to examine prospective employees; that this practice tended to transfer the determination of employment into the hands of the doctors, increased unemployment, and must create a pool of permanently unemployed persons, especially if the medical fitness required was of a progressively high standard.

Mr. BEVIN replied that his policy was to encourage the greater use of doctors' services in industrial establishments in the interest of the medical welfare of the employees. He had no evidence that this led to the imposition of unnecessarily high standards of physical fitness in prospective employees. He could not undertake to inquire at this stage whether pressure was brought to bear on employers by the insurance companies dealing with workmen's compensation so as to avoid compensation risks. He had an arrangement that a man who passed out of employment through injury or was unsuitable to go back into the employment was taken over immediately for training in some other employment.

EPIDEMIOLOGY SECTION

INFECTIOUS DISEASES AND VITAL STATISTICS

Army Medical Services

On Oct. 19 Mr. HAMMERSLEY asked the Secretary of State for War if he had considered the complaints reaching him concerning inadequate medical attention in the armed Forces. Sir JAMES GRIGG replied that individual complaints about the Army medical services reached the War Office from time to time from various sources. The complaints were always investigated, and in most cases were found to be without foundation. When there was ground for complaint it was the fault either of an individual or of the local administrative machinery, and action was at once taken to avoid repetition of the fault. He was not, however, aware that there was any body of complaint about the general organization and administration of the Army medical services. In general, considering the special difficulties with which Army doctors had to contend and the impossibility of meeting the Army's full requirement to ensure that medical officers at home were used to the best advantage of the Army. An investigation was now proceeding by all ranks to the officers at home borne out by tributes paid by the Army over-seas. His view was borne out by the medical services with the Army. Sir James Grigg also told Mr. Hammersley that, without notice, early diagnosis of tuberculosis in the Army.

Accidents in the Mine.—During a debate on the coal-mining situation, Mr. THOMAS SMITH said that in 1943 to date 542 men and lads had been killed. For the same period last year the figure was 689. Progress had been made in treating fracture cases. To-day facilities for rehabilitation were provided in every colliery district; there were eight residential centres. For every man injured in a factory six men were injured in the pit.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales scarlet fever, measles, and acute pneumonia became more prevalent during the week, notifications going up by 293, 116, and 148 respectively. Those of whooping-cough and dysentery fell by 102 and 74.

The small general rise in the notifications of measles ends the continuous drop in incidence that has lasted for the past seventeen weeks. Although there were only 8 more cases of diphtheria than in the previous week, the county totals varied considerably. In the south (London, south-eastern, and south-western divisions) the combined total rose by 42. The only notable decrease was in Durham, with 50 cases in Middlesex. Whooping-cough incidence was down by 23 in Middlesex; the only noteworthy exception to the general trend was a rise of 37 in Essex. The increased prevalence of acute pneumonia was fairly general, the largest rises being 22 more cases in Durham and 21 more each in Lancashire, London, and Yorks West Riding.

Notifications of scarlet fever are now double what they were seven weeks ago, and the 3,249 cases now recorded (week ending Oct. 9) form the largest number for several years. The largest weekly total in each of the six years 1937-42 was: 2,717, 2,463, 2,012, 2,027, 1,419, 2,979. The biggest rises during the week under review were in Lancashire by 73, Yorks West Riding by 38, Essex by 52, and Kent by 35.

Despite the fall of 74 cases in the weekly figure for dysentery, the notifications exceed 260 for the fourth consecutive week. Notifications dropped in three of last week's epidemic areas—London 91 to 52, Lancashire 42 to 20, Essex 33 to 17—while there was a small rise in the fourth area, Kent, from 57 to 59. In several other areas there were increases, chiefly in Yorks West Riding by 18, Middlesex by 14, Hertfordshire by 12, Yorks North Riding by 9, and Gloucestershire by 11.

In Scotland there were 34 more cases of dysentery, 41 of whooping-cough, and 22 of acute pneumonia; diphtheria incidence was lower by 25 cases. The increase in dysentery was mainly due to an outbreak in Dunbarton County, where the cases rose from 4 to 42. The largest of the other centres of infection were the cities of Glasgow, 12, and Edinburgh, 11 cases. Of the 181 notifications of whooping-cough 120 were recorded in Glasgow.

In Eire the increase in diphtheria of 33 cases was spread generally throughout the country.

In Northern Ireland 60 of the 95 cases of scarlet fever were notified in Belfast.

The Week Ending October 16

The returns of infectious diseases in England and Wales during the week included: scarlet fever 3,324, whooping-cough 1,482, diphtheria 707, measles 675, acute pneumonia 569, cerebrospinal fever 37, dysentery 253, paratyphoid 3, typhoid 5.

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 9. Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The Food Education Society announces a lecture by Prof. J. R. Marrack, M.D., on "Food and the Post-war World," to be given on Nov. 15, at 3 p.m., at the London School of Hygiene, Keppel Street, W.C.1.

After the annual general meeting of the British Social Hygiene Council, to be held at B.M.A. House, Tavistock Square, W.C.1, on Monday, Nov. 1, at 3.30 p.m., the president, Sir Walter Langdon-Brown, will give an address on "Social Biology and Planning."

A council meeting of the Medical Superintendents' Society will be held at the Midland Hotel, Derby, on Saturday, Oct. 30, at 2 p.m., and continued on Sunday, Oct. 31, at 10 a.m. and into the afternoon if necessary.

The Princess Tshahi Memorial Hospital Council, of which Lord Horder is the honorary treasurer, will hold a reception to General Sir William Dobbie of Malta at the Dorchester Hotel, Park Lane, W., at 3 p.m. on Thursday, Nov. 4. Lord Davies will preside and the Princess Tenagne Haile Selassie of Ethiopia hopes to be present.

Post-war nutritional relief is to be the subject for discussion at a whole-day conference of the Nutrition Society on Saturday, Nov. 6, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1. The chair will be taken by Lord Horder. In the morning Prof. J. R. Marrack, who is on the Committee for Co-ordination of Nutrition Surveys, will speak about experiences of the last war and since, dealing especially with the current state of nutrition in occupied Europe and elsewhere. A discussion on this paper will be opened by Surg. General Dr. K. Evang of the Norwegian Ministry of Social Welfare. Mr. J. Hammond, D.Sc., F.R.S., will then speak on problems of production in relation to post-war nutritional relief. In the afternoon Dr. Audrey Russell will speak on the organization of nutritional relief in the field, the discussion on this subject to be opened by Prof. E. Nobel, M.D., formerly of Vienna University. The last paper of the afternoon will be by Miss E. M. M. Hume on opportunities for nutritional research in the work of relief. Proceedings will begin at 11 a.m. promptly. Non-members are admitted only through a member's introduction.

The council of the Liverpool School of Tropical Medicine has decided that the sum of £500 placed at its disposal by Sir Robert Rankin, M.P., to commemorate the scientific work of the late Prof. Warrington Yorke, M.D., F.R.S., shall be used to provide a memorial medal, to be awarded twice yearly on the result of the examination held at the end of each of two courses for the Diploma in Tropical Hygiene.

Survivors of the hospital ship *Newfoundland*, which was set on fire and sunk off Salerno on Sept. 13 by a German bomber, stated on their arrival at a Scottish port that the vessel was deliberately singled out for attack. All her lights were on and the Red Cross was clearly visible. There were no wounded on board; but six nurses, all the doctors, and the ship's officers lost their lives. The death-roll totalled 23; the dental surgeons on board escaped. The *Newfoundland* caught fire after a direct hit, and the evacuation of all those whom it was possible to save was effected by members of the crew. Orders were given to abandon ship, and all efforts were concentrated on removing the sick, many of them stretcher cases. In this task doctors and nurses worked heroically. At the time of the bombing the *Newfoundland* was carrying as passengers about 100 American nursing sisters who were to land with the Fifth Army.

The September issue of the *Archives of Disease in Childhood* contains two reports by the British Paediatric Association: one on "The Early Diagnosis of Tuberculosis in Childhood," and the other on "Arrangements for Newly Born Babies in Maternity Hospitals." Copies of these reports may be obtained from the Acting Hon. Secretary of the British Paediatric Association, Dr. Donald Paterson, 27, Devonshire Place, London, W.1.

The second East Asiatic Medical Congress was recently held in Japan and was attended by 300 delegates from countries at present in Japanese occupation. The subjects principally discussed were the campaign against tuberculosis and tropical diseases.

The Mackenzie Mackinnon Research Fund Committee has appointed Miss J. M. Dollar, M.S., F.R.C.S., of the London School of Medicine for Women and the Royal Eye Hospital, to a research fellowship.

The late Dr. William Hartley Tattersall of Deganwy, Caernarvon, who left £111,718 (net personality £102,316), bequeathed £500 to the Royal Medical Benevolent Fund.

Local authorities are to be allowed a further year, from March 31, 1944, to March 31, 1945, during which they may submit their plans under the Cancer Act, 1939.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Aitology Westcent*, London; SECRETARY, *Mediscra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Osteo-arthritis after Colitis

Q.—Is there any useful practical treatment for early osteo-arthritis with painful "locking," in one knee? The patient is a man 60. Colitis has been present for many years following a typhoid, dysentery. This has improved enormously with the onset of knee trouble. There is definite swelling around the affected knee but no appreciable fluid in the joint. There is some resistance to the outer region of the popliteal space. Extension of the joint is somewhat limited.

A.—The active condition in this case would appear to be a violent synovitis, probably infective in nature and associated with colitis. Arthritis is often a sequel of dysentery, and the inflammation in the colitis with the onset of the knee-joint trouble is suggestive. A thorough bacteriological investigation by an expert in tropical diseases would be worth while; if positive, sulphaguanamide should be given a thorough trial. An endocrine disorder is a possible factor; villous synovitis is the pathological condition of the arthritis of the menopause. Osteo-arthritis has presumably been diagnosed from the presence of exostoses revealed by x-ray examination, but these are unimportant unless actually interfering with movement of the joint. A blocked leather splint to support the joint would control the tendency to "locking." The limitation of extension would probably prevent the use of a Howard Marsh splint with a hinge to permit flexion, which could be fixed in extension. An alternative which might be more effective if the patient would tolerate it would be a walking calliper transmitting the weight from the hip to the heel of the shoe; this would give support to the knee and permit the synovitis to settle down, and the swelling would improve or disappear. Short-wave therapy often relieves pain, or ionization with T.C.P., providing the ions of chloroiodine, and salicylic acid, is useful. In some cases the electrocautery has proved effective when other methods have failed—old farrier's practice of "firing" a horse.

Suppressing Lactation in Puerperal Fever

Q.—What is the best method of suppressing lactation in a case of puerperal fever? The administration of large doses of stilboestrol by the mouth at the same time as the patient is concurrently deavouring to assimilate full doses of sulphonamide does not seem to me desirable.

A.—Pregnant and recently delivered women tolerate large doses of oestrogenic substances. Hexoestrol tablets do not produce toxic effects that stilboestrol sometimes produces. For suppression of lactation by injections one would suggest oestradiol benz (50,000 units) three times during the first week on alternate days.

Pernicious Anaemia of Pregnancy

Q.—A patient 4/12 pregnant developed pernicious anaemia in pregnancy. The response to liver therapy by injection was satisfactory. The last injection was given 3/52 before the birth due, and she developed a very mild urticarial rash which was reported until after the birth. During labour she had 1 unit of thymophycin, and almost immediately afterwards became very ill and almost unconscious—her mucous membrane became livid. Adrenaline brought her round, but the child was born dead—anoxaemia. Now she is pregnant again, and her blood picture is good with taking large doses of pepsac. Skin tests show that she reacts to thymus, pituitary, and liver extract. If the occasion arises—say a P.P.H.—what injection, if any, can be given with safety?

A.—The fact that this patient gives a positive skin reaction to liver, pituitary, and thymus suggests that she is sensitive to protein, which is presumably the common factor. It is likely that desensitization to one of the extracts—e.g., liver extract—would be effective in preventing reactions from the others. In practice, however, it would seem preferable to avoid the use of any of these preparations, and if an emergency arises at the time of delivery

LETTERS, NOTES, AND ANSWERS

OCT. 30, 1943

P.P.H.), to give ergometrine either intramuscularly or intravenously. The administration of posterior pituitary extracts is always accompanied by the possibility of producing pituitrin shock; the clinical picture resembling that seen in this patient: the use of ergometrine is unaccompanied by such a reaction. It is of interest to note that anaemia came on early during the first pregnancy and was apparently easily controlled, whereas pernicious anaemia comes on late and may be slow to respond even to large and frequent doses of liver. Moreover, it is by no means inevitable that pernicious anaemia of pregnancy should recur in subsequent pregnancies. The diagnosis should therefore be carefully reviewed. If pepsac does not continue to be effective as this pregnancy advances, and reactions are given with a different preparation of liver, transfusion may become necessary to tide the patient over until after delivery. Note.—Pepsac is the proprietary term for desiccated stomach—the "ventriculus desiccatus" of the B.P.C. Desiccated stomach is also marketed under the following proprietary names: erythroid, eugastrol, extomak, gaster siccata, gastrexo, kytogen, ventraemon, ventriculin. This terminological confusion is to be regretted.

Glycerin in Ointments

Q.—(a) Is the use of glycerin as a constituent of an ointment or a lotion contraindicated in the treatment of industrial dermatitis or other skin disease? If no, what is its therapeutic use? (b) As glycerin is stated to dehydrate and therefore damage the skin cells, how does it effect its emollient action, and how is its use as an emollient justified? (c) Should glycerin be used at all as a constituent of barrier creams?

A.—(a) No. Glycerin is much used in lotions such as calamine to make the contained powder adhere to the skin and in emollient creams for the purpose of keeping the skin soft; also as glycerol of starch to make a non-greasy base for ointments. (b) Pure glycerin is strongly hygroscopic and is therefore irritating to an excoriated area of skin, though this property is useful in promoting exosmosis in the case of lesions such as boils and when used in tampons. When used in a lotion or emollient cream it is always diluted with water to a concentration of only 12% to 30%. In these dilutions it is not irritating. (c) It would not appear to have any particular function in a barrier cream except as forming part of the base.

Note on Schizophrenia

Q.—I have been puzzled over the terms schizophrenia and dementia praecox. The former term literally means "split mind." How may we diagnose clearly these two types of mental disturbance? Houston seems to have put both these types under the head of "Insanity of Adolescence."

A.—The two terms are synonymous for the same disorder, but dementia praecox is the older term. The term schizophrenia was introduced because it was recognized that a considerable proportion of the cases did not proceed to dementia, but on the contrary made a more or less complete recovery. It is now customary to speak of schizophrenic dementia instead of dementia praecox in those cases in which the end-result is chronic mental deterioration of a severe degree. The diagnosis in the condition as a whole is made on a symptom-picture in which at least the beginning is characterized by disturbance both of its form and of its content. Thinking shows disturbance both of the extent of incoherence, that is to say, it is disconnected often to the extent of incoherence, and it consists of a considerable variety of morbid ideas amounting to delusions, never well knit together and often characterized by oddity. Hallucinations are common but not invariably present, and are likewise apt to have a fantastic air about them. As time goes on the delusions and hallucinations in a deteriorating case become even more fragmentary and poorly knit together, until finally only a few relics of the old notions are left. Behaviour is altered from the beginning, either in the direction of increasing withdrawal and exclusiveness and occasionally very excited and impulsive behaviour. Again, in the typical deteriorating case the patient settles down to a largely vegetative existence. The inquirer should refer to Henderson and Gillespie's *Textbook of Psychiatry* (5th edition, 1940) for further information.

Lock Hospitals

Q.—Can you tell me the origin of the name "lock" as applied to "lock" hospitals for venereal diseases?

A.—Four possible explanations have been given for the origin of the word "lock" in this connexion. (1) The use of a lock of hair in ancient times to arrest haemorrhage. (2) The situation of the female lock hospital near the lock bridge. (3) That the name of the founder was Lock. (4) That the patients were kept under lock and key. These explanations seem rather weak, and have little to support them. The following information very kindly supplied to me by Mr. Johnston Abraham seems much more reliable. "The origin of the name 'lock' is obscure. There is no doubt it was applied to

the old lazaret houses for leprosy in the Middle Ages, and when syphilis became a menace and leprosy died out it was transferred to the venereal hospitals. Anson, who was a pupil of Ricord, states in his book on prostitution that the name is Norman French, and is a corruption of 'Les Loches,' the lazaret houses. There is an engraving of the old Lock Hospital in the Borough founded by Edward VI, which shows over the doorway the words 'Les Lock.' This old hospital, which was staffed from Bart's, was demolished in 1741. The name was revived by William Blomfield, surgeon to St. George's Hospital, when he founded the present Lock Hospital in 1746. That, I think, sums up all that is known about the name. One thing is certain: it has nothing to do with locking people up."

Undescended Testis

Q.—Until what age in childhood should the condition of undescended testis be left untreated in expectation of spontaneous cure? What treatment, short of surgical correction, should then be provided?

A.—Until the approach of puberty. A large number of hidden testicles descend spontaneously then. Treatment with chorionic gonadotrophin will frequently bring them down earlier, but it is unnecessary in so large a proportion of cases that it is not justifiable, although the risk of producing a precocious puberty has been exaggerated. At the age of about 12 or 13, 500 rat units of chorionic (urinary) gonadotrophin should be given intramuscularly twice a week until descent occurs or three months' treatment has been given. If then the testicles have not descended they are truly ectopic, and operation should be performed without further delay.

Blocked Tubes

Q.—A woman aged 33, married seven years, no children, h. tuberculous peritonitis at the age of 15. Eighteen months after marriage she had what seemed to be an abortion. Recently laparotomy was made to gauge the patency of her tubes by injecting lipiodol into the uterus. Both tubes were blocked at a distance of about 1½ in. from the isthmus of the uterus. She has recently also been examined for T.B., even though she showed no symptoms of this disease, and the opinion has been expressed by the physician that the tuberculosis is quiescent and that there is no danger of lighting up the old disease. Is there any hope, by means of air insufflations over a period of time, of opening up the tubes, or is there any alternative treatment?

A.—The history suggests that the tubes have been obstructed by tuberculous salpingitis associated with peritonitis. If, however, it is certain that this woman did have an abortion, then the tubal obstruction may be the result of post-abortion infection, with or without pre-existing tuberculosis. In either case air insufflation at it pressure insufficient to rupture obstruction, and any attempt at it coming a complete mechanical obstruction, would be likely to cause an acute exacerbation of the infection. The only possible line of treatment is salpingostomy by abdominal operation, and, with the obstruction half-way along the tube, the chances of this being successful are remote. If the infection is tuberculous in nature the outlook is hopeless, and in view of this possibility it would probably be wiser not to undertake any further treatment, thus avoiding the risk of activating a quiescent condition.

Reaction to Potassium Chloride

Q.—With reference to the question on chloride of potash in allergy (Oct. 2, p. 440), what are the "extremely uncomfortable" side-reactions mentioned in the reply?

A.—Although it was formerly believed that potassium salts were excreted too rapidly to produce any side-effects, more and more evidence has recently accumulated that such may occur, particularly with high dosage and in patients with cardio-renal disease. Symptoms described include gastro-intestinal irritation, paraesthesia of the hands and feet, cyanosis, prostration, irregularity of the pulse, heart-block, and even sudden death.

Septic Tonsils and Teeth

Q.—One often hears such expressions as "septic teeth," "septic tonsils." These diseases are not referred to in textbooks, at least in the majority of them. What exactly do the terms imply?

A.—The popular use of the term "septic teeth" refers usually to pyorrhoea which begins as an inflammation of the edge of the gums—marginal gingivitis. If unchecked the infection spreads, destroys the attachment of the mucoperiosteum to the neck of the tooth, and pockets of pus develop between gum and tooth. This condition is called pyorrhoea alveolaris. Another infection included in "septic teeth" is the apical abscess which follows dental caries. Here the infection spreads up through the pulp cavity to the apex of the tooth-root and attacks the periodontal membrane. An acute alveolar abscess may result; more often the sequel is a chronic apical infection which can only be certainly detected by examination.

The term "septic tonsils" is often used loosely to denote any obvious abnormality, particularly enlargement, of the tonsils. It should be restricted to those cases in which there is chronic infection of the tonsils—chronic tonsillitis. Affected persons have a history of recurrent sore throat, the tonsils are not as a rule obviously enlarged, the tonsillar glands are palpable, and foul-smelling exudate (not to be confused with the harmless cheesy material) can usually be squeezed from the tonsillar crypts. Such tonsils should be excised. Tonsillar enlargement is almost a physiological happening in children, and, far from being a liability, is probably an asset by acting as a front-line filter of pathogenic bacteria—and perhaps by manufacturing antibodies, for there is evidence that the lymph nodes take an active part in antibody production. Fortunately there is now a reaction against wholesale tonsillectomy among children.

The Injured Diabetic

Q.—I note that in "Any Questions?" (Oct. 9, p. 472) your expert advises: "If the diabetic is uninjured, deal with him like any other injured person, as he is very unlikely to be suffering from hypoglycaemia." Is it not a fact, then, that hypoglycaemic coma is likely to be brought on by severe mental and physical stress and pain, and is definitely more sudden in onset than diabetic coma? I should appreciate confirmation on this point.

A.—It is very unlikely that hypoglycaemic coma can ever be brought on by severe mental or physical stress and pain, because in these conditions it is believed that there is an outpouring of adrenaline to combat the condition. The adrenaline will inevitably send up the blood sugar and will therefore tend to prevent the onset of hypoglycaemia. All these three conditions are therefore much more likely to cause glycosuria. It is, of course, possible that a patient who has run to a shelter without having the carbohydrate of her meal, or who has taken a wrong dose of insulin, or who is liable to sudden attacks of hypoglycaemia, might develop an attack of hypoglycaemia during an air raid in spite of the outpouring of adrenaline produced by physical stress and pain. A "faint," on the other hand, may well be brought on, and the patient should, of course, recover quickly. It is most important to treat any diabetic person who becomes unconscious during an air raid as having hypoglycaemia and to give sugar to drink or, if necessary, intravenously. Hypoglycaemia always comes on very suddenly, and the point of distinction between it and diabetic coma is the well-being of the patient until just before the onset of unconsciousness. In diabetic coma, on the other hand, there is nearly always a history of an illness of twenty-four hours' or more duration, often, unfortunately, coupled with the omission of the insulin because the patient cannot eat any food. The onset of coma is always gradual.

Precancerous Stage

Q.—What is known of the precancerous stage of cancer?

A.—Cancer develops with high frequency in certain gross lesions which, commonly, are described as precancerous. In general the transition occurs abruptly in a lesion of long standing and it is not inevitable. Distinctive lesions, in the strict sense precancerous, which necessarily precede and always culminate in cancer, are hard to identify. In the experience of most investigators the first unequivocal evidence of the action of carcinogenic agents in experimental animals has been the development of minute tumours after a latent period of weeks or months during which the response of the tissues is not demonstrable by methods hitherto used.

Polyuria in Old Age

Q.—Is there a tendency to polyuria with increasing age? A man aged 68 has to urinate twice during the night. The urine is clear and perfectly normal, the stream good, and there is no difficulty in starting. There are no signs or symptoms of enlarged prostate except perhaps slight delay in finishing micturition. Blood pressure is 130/75. Little fluid is taken in the evening. The quantity of urine is rather large.

A.—A tendency to nocturnal polyuria with increasing age may be an early expression of diminution in either the cardiac or the renal reserve, resulting from arteriosclerosis. When the origin is cardiac there is usually oliguria during the day; the recumbent posture at night diminishes the venous engorgement of the lower extremities, with consequent elimination by the kidneys of occult oedema fluid which has accumulated during the day. The specific gravity of the nocturnal urine is high, and there should be confirmatory evidence of diminished cardiac reserve, such as diminished exercise tolerance. When the origin is renal, the polyuria compensates for diminished "flexibility" of the kidneys and is the result of arteriosclerotic ischaemic fibrosis replacing functioning renal tissue. A specific gravity concentration test shows inability to secrete a highly concentrated urine. There is some polyuria during the day and the nocturnal urine has a low specific gravity. In this patient—if it is assumed that the symptoms are not due to prostatic obstruction and there are no other symptoms which suggest an unduly diminished cardiac reserve—it is reasonable to regard

the cause as being arteriosclerotic diminution of renal reserve; as to regard the patient as having kidneys corresponding to Clifton Allbutt's description of a "starved but not a corrupt kidney sufficient for the smaller life of an elderly man."

LETTERS, NOTES, ETC.

Pruritus Ani

Dr. F. SUGDEN (Kingsclere) writes: With reference to the note on pruritus ani in the "Any Questions?" column of the *Journal* (Sept. 25, p. 410), might I recommend a treatment inaugurated by my partner, Dr. D. N. Philip, when he was H.S. at the Prince Beatrice Hospital? This consists of repeated painting of the affected area with Castellani's fuchsin paint. I have seen this clear completely several very severe cases of pruritus ani, and I have to see a relapse.

Mr. J. LIVINGSTON (Barrow-in-Furness) writes: Local application of calomel powder (plus scrupulous cleanliness) is one of the oldest and best remedies, and this treatment has been published in the *Journal* from time to time for years.

Dr. A. GREENE (Norwich) writes: I have had experience of the distressing complaint being cured by the application twice a day for a few weeks of ung. metallorum.

Nipples and Breast-feeding

Dr. MARY G. H. EDWARDS (New Milton, Hants) writes: I feel I must supplement your answer to the query on cracked nipples. I have learnt that these are due to allowing the infant to remain too long on the breast during feed-times for the first 2 or 3 days. Two minutes on the first day, three the second, five on the third are as much as a nipple can be expected to stand. Nipples can be hardened by leaving soap on them, from the seventh month rather than washing off the soap; but even untreated nipples will not crack if not over-used at first. Depressed nipples can, in extreme cases, be made to function by the diurnal use of a breast pump, from the third month of pregnancy if possible, and this treatment is far more efficacious than massage.

Treatment of Gonococcal Arthritis

Mr. J. F. PEART, F.R.C.S. (Sandbach, Cheshire), writes: In your issue of Aug. 28 a question was asked in connexion with the treatment of gonococcal arthritis. I noticed that prostatic massage was being carried out and recommended. As I pointed out in a paper read to the International Congress of Hygiene in 1928, the most satisfactory treatment of gonococcal rheumatism is vasotomy. It is also the rational treatment for the condition is evident when it is realized that the infection is lodged in the seminal vesicles. I consider massage of the prostate useless, if not actually harmful, likely to cause a dissemination of the poison, besides being painful for the patient when the prostate is tender. Massage of the vesicles would be more rational, but unfortunately it is impossible in many cases to reach the fundus of the vesicles, so that expression would be imperfect. In my experience these cases clear up after vasotomy has been performed, cessation of pain and gradual subsidence of the swelling in the joints resulting. That vasotomy may cause sterility is a myth, for I have had cases showing spermatozoa in their semen six months after the performance of double vasotomy.

Temporary Tonic Motor Paralysis

A paper by G. de M. Rudolf on a condition believed hitherto described has been deposited in the library of the Royal Society of Medicine. This paper may be consulted by any who are interested; but as the condition is probably of a psychological nature, it is considered unwise in the national interests to publish a description of it until after the close of hostilities.

Salmon in the Thames

Dr. HERBERT C. JONAS (Braunton) writes: The leading article in the *Journal* of the Rivers of England (Oct. 9, p. 457) once more refers to the story of the glut of salmon and the indenture of the apprentice. The author has clearly not read all the evidence. Frank Buckle wrote the final word. When he was inspector of fisheries he offered £50 for a copy of this much-quoted document. Once when in Exeter he heard of an old lady who actually had a copy. She lived in the middle of Dartmoor. Buckland hired a carriage and pair and drove off next day. He saw the old lady and asked to see the copy. Her answer was: "Wull, there now, durm me ef I do burn the thing last wick when I were spring clanin'."

Disclaimer

Dr. E. WRIGLEY BRAITHWAITE (Leeds) writes with reference to some press publicity following his letter in the *Journal* of Oct. (p. 433): What was made to appear as an interview with me in the columns of one paper was derived from a phone conversation only, in which I refused to make any statement and forbade a comment under my name on my letter. I subsequently refused to give any assistance or information on five occasions.

TREATMENT OF GUNSHOT FRACTURES OF THE LIMBS

BY

Prof. SERGEI S. YUDIN, F.R.C.S.(Hon.)

Surgeon to the Skljassovski Hospital for Traumatic Diseases, Moscow

General Considerations

The experience gained during eighteen months of the present war has revealed the advantages and disadvantages of the various methods of treatment for gunshot fractures of the limbs. From these preliminary data the results of therapy can be assessed, and general rules can be laid down for the treatment of these fractures, both in the field and at base hospitals.

The methods used are based on three main therapeutic factors: wide surgical excision of the wound; adequate local and general use of sulphonamides; prolonged fixation in plaster. These principles are indisputable, and surgical excision should not be replaced by chemical sterilization or the introduction of packing. In addition the application of dry sulphonamide powders is immeasurably better than the use of other antiseptics or repeated irrigations, and allows adequate splinting with plaster, which is essential for complete immobilization of the limb. This immobilization is of paramount importance in the case of gunshot fractures, especially of the femur, not only for procuring adequate union of the fracture and healing of the wound but for the survival of the limb and even the patient. Not only is immobilization in plaster the most important factor in the treatment but it is most suitable for the transport of the patient over long distances.

Immobilization by extension has undeniable merit. Its great advantage is its application to almost any case of fracture or dislocation, and by it satisfactory reduction can be obtained even after delay in therapy; but even in the treatment of closed fractures such procedures are impossible when the patient has to be moved repeatedly from one place to another. The amount of time and trouble expended in the autumn months of 1941 on moving patients to and from air-raid shelters was enormous and the effectiveness of treatment was greatly impaired. In addition in times of stress it is difficult, if not impossible, to use methods of extension at advanced casualty stations, and by the time such patients have reached a base hospital union is so complete that correction by traction is no longer possible. Moreover, with infected fractures it is difficult to secure adequate rest for the patient, and the healing of the wound and fracture is impaired by repeated dressings and movement in bed. This not only retards recovery but jeopardizes the final result, and the more rapidly healing occurs in both soft tissue and bone the greater preservation of function there will be. On the other hand, the slower the resolution of the infection the more scar tissue there will be, and final function will be less, particularly in the case of the knee-joint.

We do not consider it possible to procure adequate immobilization of the bone fragments and soft parts with hinged splints and other forms of apparatus; in fact, these defects are present to a greater degree with such apparatus than with skeletal extension, since they cannot be fitted securely enough and are apt to become displaced. Plaster-of-Paris bandages are applied direct to the skin and immobilize the whole limb, thus securing maximum rest and allowing easy transport; the nursing is thereby simplified and the work of the surgeons lightened.

Plaster Fixation

There are, however, some important defects and drawbacks in this method of treatment, and we would point out its limitations for general application. The three main drawbacks are: (1) the defective position of the bone fragments may not easily be seen and serious shortening of the limb may result; (2) contractions and stiffness of the joints may occur; (3) sepsis may progress unnoticed. I shall consider each of these drawbacks separately.

Shortening of Limb.—Should an unreduced fracture with serious displacement and shortening occur, it is not the fault of the method but of the surgeon who allowed this to happen during application of the plaster. In cases of gunshot fractures displacement of the fragments and shortening are as a rule slight, and good alignment is usually possible in any part of the limb after the excision of the wound. This, however, does not apply to fractures close to joints, in particular the knee-joint. In most cases a good position is obtained by manual reduction before the plaster-of-Paris is applied, but 20 to 25% of gunshot fractures of the femur show considerable deformity which cannot be eliminated in this way; in such cases a light extension apparatus with a screw extension is required.

The application of plaster-of-Paris necessitates a certain skill, and the successful use of an extension apparatus requires a knowledge of orthopaedic surgery, though not more than the use of weight extension.

There are still some cases in which one cannot avoid anterior displacement, and sometimes in order to avoid shortening it is necessary to insert a pin as well as using plaster. Such a method of forced extension and plaster in combination (as used by Winnett Orr) sometimes admits of correction of deformity even up to periods of three to six weeks after the injury. Even in such cases fixation in plaster has many advantages over skeletal traction by weights, as in the latter the amount of weight required is enormous and the length of time in bed much prolonged; in addition evacuation from one hospital to another is facilitated. Consequently the first alleged defect does not in fact exist.

Contracture and Stiffness of Joints.—The statement that plaster fixation causes contracture and stiffness of joints is wrong; immobilization by this means causes harm neither to joint surfaces nor to the healing process; the real cause of the contracture is scarring in the muscles as a result of injury and infection, and the adhesion of damaged muscles to the site of fracture and callus. In injuries to the femur the wound is generally in the quadriceps femoris, and this explains the frequency of extensor contracture of the knee-joint. All along, the quadriceps lies close to the bone, but the flexors are further away from the femur and thus are less often involved, consequently flexor contracture is less common.

I would also mention that gunshot wounds of the leg are treated in the same way. An extensor contracture of the knee-joint never occurs although immobilization may last for months, and this method of fixation cannot be blamed for the impaired function of the knee-joint, but indeed seems to be the best means of treating both the fracture and the muscle injury, and securing the least amount of deformity.

Suppuration beneath Plaster.—The most serious disadvantage alleged against plaster fixation is the impossibility of seeing the extent of suppuration under it. This, it is suggested, gives rise to the risk of neglecting appropriate treatment for the sepsis at any given time. Such fears are groundless in many respects; the degree of infection may be judged by the general disturbance, both subjective and objective, as well as by direct observation of the wound, and frequent dressings following wound examination

are harmful. Moreover, plaster bandages have proved themselves to be very absorbent. A great drawback is the odour, which is a small factor when it is compared with the advantages this method affords.

Procedure in Plaster Fixation

Anyone, in fact, who uses this method for gunshot fractures will never wish to return to any other. The condition of the wound and the granulation tissue which develops under the plaster are remarkable. I will not now endeavour to explain the wonderful reparative power of the tissues under such treatment, but will merely point out that no other method produces such rapid sterilization of wounds, granulation of cavities, and rapid epithelization. It should be emphasized, however, that the plaster must only be put on after wide excision of the wound and removal of all dead and damaged tissue. If this is not done, whatever the method of treatment used, fatal infection may occur; but, even under adverse conditions when such treatment is impossible, no other method has given results as good as immobilization in plaster. In this method all surgical procedures preparatory to fixation must be suitable for the application of plaster over them. The extent of the operative procedures varies according to the time of the operation after the initial injury—that is, in relation to the degree and spread of infection.

Early Cases.—If operation is performed early and the wound is not yet clinically infected—that is, on an average within six to eight hours—the procedure is confined to the removal of all large foreign bodies and blood-clot, and a thorough excision of all devitalized tissue. Bone fragments need much care, and only loose fragments should be removed. Bone still adherent to the periosteum or to muscle must be preserved. In such cases this operative procedure allows of relative sterilization of the cavity. Excision of the surrounding muscles should be sparing and only such muscular tissue be removed as is in danger of necrosis. After the excision no stitches should be used either in skin or in muscle, and the wound must be freely opened throughout to allow of free drainage of exudate. Hence there is no great need for accessory drainage through undamaged tissues. Next the whole cavity must be liberally filled with a sulphonamide powder, carefully ensuring that no part is missed. The limb is then encased in plaster over the open wound, no dressing being applied, and the healing of the wound should proceed without gross infection.

Cases in Later Stages.—In gunshot fractures of the thigh which are brought to operation at a later stage there will be found various degrees of infection. Some cases, though 24 to 36 hours may have elapsed from the time of trauma, are afebrile, show little clinical evidence of infection, and the discharge from the wound is not grossly purulent and has no smell. Other cases show purulent discharge, though the general condition of the patient is good and the infection appears localized. Both these types of case, if it be found at operation that the process of suppuration has not spread far beyond the wound, can be treated in the same way as the first group.

Suppurative Cases.—The third main group consists of cases which show gross infection spreading far beyond the wound itself. Under such conditions a wide excision to allow free access to the site of the fracture is absolutely necessary so that drainage is free. Lateral drainage may be needed in some cases if the wounds do not easily permit dependent drainage. The operation is designed to produce a funnel-shaped cavity with the summit at the site of fracture and the wide base on the surface of the thigh, and this should be established for both entrance and exit sites of the wound.

(I should here emphasize the preparatory cleansing of the wound with water and soap, which is widely used by English and American surgeons. We consider that adequate use of soap and water around and in the wound is of the greatest importance, and I will describe its use in detail at a later stage.)

This third group of cases consists of patients with severe suppuration at the site of fracture and spreading infection beyond the damaged area. They arrive for operation from the fifth to the fifteenth day after the fracture, showing not only local suppuration but severe signs of toxæmia. Until quite recently it was doubtful whether such cases should be treated by wide excision of all necrotic material or whether it was advisable to leave the wound completely

alone. After many operations it was found possible to put the limbs in plaster and treat them in the same way as the previous groups, and there is now no question as to the right course. The technique of wide excision down the site of fracture as previously described is of extreme importance, as is adequate use of a sulphonamide powder, both locally and by mouth. In such conditions immobilization in plaster is irreplaceable by any other means of fixation. In the present war, experience has shown that the majority of gunshot fractures have arrived for treatment when infection is far advanced. It has therefore been a matter of great importance to evolve this technique and to make available our present knowledge to all doctors dealing with Service cases.

Pre-operative Treatment

When the men first arrive at the hospital their general condition must receive attention. Many have had long journeys over bad roads; they are often physically exhausted, worn out by pain, and suffering from exposure to cold. They frequently show marked signs of shock and hæmorrhage. Many have not slept for several days and nights, and some are starving. Immediately on their arrival, therefore, general treatment must be started. The application of warmth is of great importance, and this factor is often not sufficiently appreciated. Operation may have to be postponed for several hours, during which time they are warmed and their shock is treated. Drinks such as sweetened tea, spirits by mouth, and the application of hot-water bottles and warm woollen or fur blankets often improve their condition enormously, and special resuscitation departments should be established in all base hospitals. Such departments have proved of inestimable value in the preparation of the patients for adequate surgical treatment. Blood transfusion or the infusion of glucose or saline solution may be required in a large number of cases, especially in conditions in which the blood pressure is much lowered, and a considerable blood loss.

Anæsthesia

The problem of anæsthesia must be considered in detail. It would be ideal if anæsthesia could be induced immediately after injury—that is, before first aid is applied—and continued during transit to hospital. There is no doubt that the administration of morphine, 10 mg., before first aid, and again before removal to hospital, would considerably ease the patient's discomfort and lessen the inevitable shock. This administration of morphine may again be necessary before surgical procedures are undertaken; but, if conditions permit, it is advisable to treat the shock and to undertake measures such as radiography and nursing procedures before starting any operative procedure. The operation will need complete surgical anæsthesia, and will have to be maintained during the application of the plaster while the patient is on an extension apparatus or an orthopaedic table. For the latter morphine may suffice. The time available and the order in which these procedures are undertaken determine the mode of administration of morphine and dosage. Thus, if time allows, subcutaneous morphine given a quarter of an hour before will suffice, but if anæsthesia is required urgently the intravenous injection of 1.5 to 2 c.c. of a 1% solution of morphine, or, better, the Kirschner mix (morphine hydrochloride 0.25 g., scopolamine hydrochloride 0.025 g., narcotine hydrochloride 1.25 g., ephedrine hydrochloride 0.25 g., and 0.75% sodium chloride 100 c.c.m.) give considerable analgesia and even sleep. If the operation requires the administration of a general anæsthetic preliminary medication will aid in the induction and reduce the amount of general anæsthetic required, and, moreover, lengthen the anæsthesia so as to allow ample time for subsequent drying of the plaster.

Local anæsthesia in cases of gunshot fractures of the limb has a very limited application. There is no doubt that injection of local anæsthetic into the fracture site and surrounding hæmatoma is of great value if it can be used, in the conditions under discussion it is sometimes very difficult to ascertain the exact site of the fracture without prolonged and careful examination, which is often impossible, and certainly undesirable. Secondly, with open fractures it is difficult to maintain the solution of local anæsthetic at the fracture site. In a few cases of closed fracture it may be of some value. Local anæsthesia for the excision of a wound is open to serious

jections. The injection at the local site is difficult, and in consequence it is often impossible to ensure anaesthesia. It is so often impossible to determine beforehand how extensive an excision will have to be, and so during the operation there may be constant delays while fresh areas are anaesthetized in order to complete the operation successfully. Moreover, the infiltration of the local anaesthetic conceals the natural appearance of the muscles and makes it difficult to determine how much muscle tissue has been damaged by the injury and in consequence how much muscle should be excised. We consider, therefore, that the use of local anaesthesia not only impedes an operative procedure but, in open fractures, restricts the accuracy with which one can assess the extent of the damage and infection in the tissues. There is yet another consideration. The patient after operation is in an uncomfortable position for a considerable time while the plasters are setting, whether he be on some form of extension apparatus or on an orthopaedic table, and this position is exceedingly irksome and tiring, particularly to patients who are exhausted even before the operation is begun. Under these conditions the surgeon may be tempted to allow the removal of the patient before the plaster is firm; this would entail considerable risk of soiling the plaster, and the whole process might have to be repeated from the beginning. It may often prove that, even after local anaesthesia, general anaesthesia would be required during this stage and the benefit of the former lost. Finally, local anaesthesia for such complicated operations is time-consuming, and under conditions of war it is unfair to delay so long, as many other operations of equal urgency may hereby be postponed, with grave risk to the waiting patients.

Ether, with preliminary administration of morphine, provides an excellent and simple method of anaesthesia and allows complete freedom for the operator, both in the extent of the operation and in the time required. There is, of course, no reason why local block in large nerve-trunks with novocain should not be employed in addition if thought necessary. Ether should not, however, be used if the patient is suffering from bronchitis, which is not infrequent during the autumn months. It is also necessary to take adequate precautions in case of fire.

Evipan intravenously is an excellent anaesthetic, but for prolonged use the services of a skilled anaesthetist are required. This is overcome to some extent by the use of a 2% solution instead of 10%; it can be given up to 200 c.cm. by subcutaneous injection. It is useful to bear this in mind if general anaesthesia is required during an operation begun with a local anaesthetic.

None of the previous methods offers such advantages or secures such adequate relaxation as spinal anaesthesia. This allows the most satisfactory conditions for reduction of the fracture, and adequate time for examination of the tissues and excision of the wounds and for the application and drying of the plaster. The great drawback of this method is the fall in blood pressure induced. This makes it unsuitable for patients suffering from shock and also for many others who have had considerable haemorrhage, and, since in the cases under discussion one or both of these conditions are often present, this method, although very satisfactory when used, may not be possible. Spinal anaesthesia is therefore of limited value in the early stages at casualty clearing stations, where shock and haemorrhage occur with such frequency. However, during the last 18 months experience has shown that many gunshot fractures of the thigh arrive in hospital at a late stage, and although there is often considerable infection in the wound, with signs of toxæmia, the initial shock has been overcome and the blood pressure is stable. Such patients are suitable for spinal anaesthesia. In fact, in many the condition definitely improves after induction of spinal anaesthesia, and the main difficulty encountered is the movement of the patient in preparation for the lumbar puncture. Great care must be taken in the movement of patients with fractures high up in the thigh, but we find it is possible to move them in most cases. In the last 300 fractures of the thigh which passed through our clinic we were able to use this form of anaesthesia in all cases, and I have had no difficulty with it even in front-line hospitals. A 1 c.cm. of 1% nupercaine (pericaine) and the Soviet preparation sovokain are excellent preparations. The anaesthesia takes place within a few minutes and lasts for three to four hours. This

allows the patient to be moved on to the extension apparatus without pain and also admits of adequate fixation or extension of the limb painlessly. After fixation in the extension apparatus the patient is washed with soap and water, and in the same position such operative procedures as are necessary are performed; following this, the plaster is applied. During the whole procedure the anaesthesia remains and there is no complaint of discomfort from the patient, and adequate time is available for the hardening of the plaster. If neither nupercaine nor sovokain be available, novocain, tropacocaine, or stovaine may be used instead in doses of 1.5 to 2 c.cm., but the anaesthesia will be of shorter duration. With the use of any of these spinal anaesthetics it may be necessary to inject subcutaneously 1 c.cm. of 5% ephedrine if an undue fall of blood pressure occurs.

During the last 43 years spinal anaesthesia has varied greatly in popularity. There is no doubt that the successful application of this method calls for considerable skill and experience, particularly if high anaesthesia is required, but lumbar puncture in the usual situation between the 2nd and 3rd or 3rd and 4th lumbar vertebrae, and the injection of the anaesthetic mixed with 1 to 2 c.cm. of cerebrospinal fluid, are adequate in these conditions and the patient placed again in the horizontal position. Although, therefore, spinal anaesthesia is considered inapplicable in cases with shock or following recent haemorrhage, it is of immense value during the treatment of open fractures of the thigh once shock has been relieved, even if there is well-marked infection of the wound.

Position of Patient and Cleaning of Wound

The patient should not be removed from the stretcher until anaesthesia has been induced. He should then be placed immediately on to the extension apparatus, and extension applied to both legs, with a narrow support under the sacrum. This position allows adequate access to all parts of both limbs. The first procedure is thorough washing of the skin not only of the operation field but of the whole limb. The entire area should be washed thoroughly with soap and water; any shorter method, such as painting the skin with alcoholic solution of iodine, is grossly inadequate. Some difficulties may be met with during this procedure. A fresh fracture needs much care during the cleansing, and the presence of other wounds on the limb requires special attention. We do not think it adequate to use soap and water on gauze or cotton-wool; the whole area should be scrubbed with a soft brush. By means of this the cleaning is done better and much more expeditiously. It is often advisable to protect wounded surfaces during this cleansing procedure. In suitable situations this can be done by packing with dry sterilized gauze, but in many cases it is advisable to close the wound temporarily with Michel's clips. This permits of more rapid cleansing of the skin surfaces. With skilled assistance washing can be completed in from 5 to 10 minutes, and this time includes shaving the limb if necessary. The limb is then washed with water and dried with a towel or with gauze and alcohol, and the whole operation field is painted over with iodine, the limb being isolated by means of sterile towels and any temporary stitches or clips removed. There are a few sites of injury which cannot be approached with the patient in the same position—mainly cases with wounds in the buttock and perineum. Such patients should be operated on first in the prone position, and only after completion of the operation there should they be transferred to the extension apparatus for the rest of the examination and treatment. We have, however, found that in many cases these apparently inaccessible sites are easily accessible with an operation table that admits of lateral inclination of the table itself. This has been found possible by fixing the extension apparatus to the operating table. We have designed a simple wooden stand which can be given a lateral inclination of 35 degrees. We have also designed a new model of a portable apparatus with a screw extension for both legs. These two designs form a good orthopaedic table for all the operative procedures on this type of injury.

Treatment of Recent Open Fractures of the Thigh

Even in extensive wounds with gunshot fractures of the thigh operative procedures which can be done within the first 8 to 12 hours must have as their purpose complete and thorough mechanical cleansing so that the whole wound and site of

fracture should be made sterile. To achieve this all foreign bodies must be carefully removed from the wound and a diligent search made for even the smallest fragments that may have penetrated the surrounding tissues. All damaged tissue must be removed and all blood clots, so far as is possible, taken out. This may entail a wide excision of the tissues and the removal of bone fragments. The only bone fragments which should be left are those still adherent to their periosteum. One should then take great care to ensure haemostasis. Finally, the cavity which is left should be of adequate size and situation to allow easy escape for the discharge of exudation into it.

Operative Technique of Recent Fractures

The excision of fresh wounds should be done under aseptic conditions and the operation should be carried out with strict precautions; there should be available a double set of instruments and gloves, so that a fresh set may be ready for use during the clean part of the operation when the infected tissue has been removed. The question of the excision, or otherwise, of various tissues in the wound depends on their naked-eye appearance. The light available must therefore be adequate and access to the deeper parts of the wound must be wide, so that this visual examination can be effectively made.

The approach to the fracture must then be decided. In the majority of cases adequate inspection and the provision of free dependent drainage can be procured through the wound sites. If this is not easily obtained the fracture should be explored and drained through an additional incision in a suitable area.

In cases of established infection quite small excisions of the wound may have to content the surgeon, because it may be necessary to establish lateral drainage quite apart from the main direction of the wounded surfaces; but with recent wounds this is not the case. In these circumstances there is no need for the preparation for drainage through the wound, and wide excision can be performed with impunity. There may, however, arise the question of lateral access to the fracture in order to allow adequate inspection of the tissues. If the wound cannot be extended owing to the proximity of important structures, then even with recent injuries it may be necessary to explore from another direction; such exploration should always be made from the lateral aspect of the limb. This should only be done in cases of strict necessity. In addition we believe that fresh wounds should not be stitched either in the muscles or in the skin. It is assumed that adequate treatment at this stage will prevent infection in the wound, and we need not discuss here the question of treatment of sepsis.

The amount of tissue removed depends on surgical experience and requires expert judgment. First the skin wound is fully excised; this is performed in such a way that the skin surrounding the wound can be dissected intact. From one end of the excision the skin is then dissected off with a scalpel and the subcutaneous tissues inspected; all damaged subcutaneous tissue is excised with the skin. The deeper layers of tissue are removed along with the deep fascia. Extensive removal of deep fascia is often necessary to permit adequate inspection of the muscles underneath. The opening in this deep fascia should be elliptic, with its long axis in the long axis of the skin incision, and its length only slightly less than the length of the skin incision and with the deeper-wounded structures in the centre. The incision in the deep fascia is made with a scalpel, through which the tips of Cooper's scissors are introduced; by means of incision with these scissors a wide opening in the fascia can be made and the muscle brought into view, and the wounds in the muscle can now be inspected.

When the skin and infected superficial and deep fascia have been removed the dirtiest stage of the operation is completed; fresh instruments and gloves should be used and adequate haemostasis must be secured in the freshly cut surfaces. Then all damaged and injured muscle tissue must be excised and wide access to the fracture allowed. All loose fragments and blood-clot are removed, and care must be taken to ensure that suitable drainage from the fracture site is possible through this aperture, making the wound, so far as practicable, cone-shaped, with its summit at the site of fracture and its base lateral or posterior in the limb. Sometimes this is difficult owing to the direction of the wound, but in most cases with an entrance-

and-exit wound one or other of the wound tracks can be chosen for dependent drainage. Thus, with the wide excision of skin, wide aperture in the aponeurosis, and the excision of adequate muscle tissue, not only is infection removed but adequate drainage is established. During the excision the muscle contracts, and therefore this is best performed with scissors, which tend to hold it as they cut through, when the use of the scalpel is made difficult by the retraction of the muscles as they are cut.

In deep cavities it is often difficult to distinguish the ends of wounded muscle the torn ends of which have retracted in all directions. In these circumstances the wound cavity must be stretched widely open and the main direction of destruction in muscle defined. The surgeon can then see more clearly which muscles are involved and whether their ends have retracted. If this be done systematically, from the most superficial muscles down to the most deeply situated, adequate inspection becomes possible and the surgeon can remove only destroyed muscle but muscle that may not survive owing to bruising or disturbance of blood supply. Normal muscle tissue can be recognized by the following characteristics: First, a normal colour; muscle which is dying has a dull colour, has lost its gloss, and is becoming bluish in appearance; secondly, a colour change resembling the difference between arterial and venous blood. Secondly, fresh blood exudes from the surface of a fresh incision into normal muscle, showing that the blood supply is intact. Thirdly, when the muscle fibres are cut they contract if their nerve supply remains intact. On these three signs it can be decided whether the muscle is sufficiently vitalized to be removed or not. While adequate excision is essential we must remember that all tissue, particularly muscle tissue, must be preserved if at all possible, as muscle cannot regenerate, although the remaining tissue may hypertrophy. Although this point should be emphasized it must not prejudice the principles of the excision of doubtful tissue to ensure adequate drainage. Thus it would be better to remove a part of some muscle than to endeavour to preserve necrotic tissue and it is better to make large drainage apertures through healthy tissue for the removal of blood-clot and damaged tissue than to risk leaving such at the bottom of an undrained cavity. There are, however, some limitations to the extent of excision of tissue. It is unjustifiable to expose extensive areas of either large blood vessels or nerve trunks, owing to the grave subsequent risk of haemorrhage or nerve complication. It is therefore necessary sometimes to preserve some damaged tissue in the vicinity of such structures. If these structures intersect the wound cavity an endeavour is made to clean the cavity around them, and then to protect them with a muscle covering produced with two or three fine catgut sutures or them.

Bone fragments present another problem. We have already made it clear that any loose fragments must be removed by a careful search made to ensure that none are left behind but that fragments of periosteum must in no circumstances be removed, though they may need to be replaced and the sharp edges may have to be rounded so long as the periosteal connexion is not damaged.

It is very difficult to give any definite indications with regard to the removal of fragments of bone with a dubious connexion to soft tissue. One should be careful to remove doubtful fragments so long as the amount removed does not prejudice bony union in the fracture. Provided that the rest of the operation has been done properly, it is unusual for an occasional necrotic fragment to produce a worse result than the formation of a sequestrum, which can be removed later. However, it be found impossible to perform adequate excision of the soft tissue, then it is imperative that all doubtful fragments should be removed and that great care should then be taken to leave undisturbed even the smallest portions of periosteum.

This procedure completes the operation. After this, haemostasis must be secured, and must be complete. Even the smallest bleeding vessel should be ligatured with fine catgut. The whole wound should be powdered with sulphamilamide or, better still, with a mixture of sulphamilamide and sulphathiazole. The wound should not be sutured. The plaster now applied as previously described without any dressing padding under it.

Operative Procedures in Late Cases of Gunshot Fractures of the Thigh

In this group of cases there are various types. Some do not show evidence of infection, but are assumed to be infected because of the long delay between injury and treatment. Such cases can often be treated as were those in the previous group. There are others in which wound infection is apparent but confined to the local area. Such a series also includes patients who have had an excision at an earlier stage and have been left with packing in the wound. For patients with local infection the treatment as previously described may be possible still; but if the infection is more widespread, then treatment must be different. The operation in this case is designed not for wide excision but for adequate inspection and cleansing of the site of fracture and the securing of adequate drainage from the wound cavity. In this connexion the situation of the wound is of great importance. Thus wounds on the outer side or on the posterior surface of the limb frequently permit of adequate dependent drainage, whereas wounds on the interior or anterior surface of the limb are often quite unsuitable not only for drainage but even for adequate inspection of the damaged tissue. Thus it is sometimes necessary to explore through an incision on the outer side of the limb and to establish drainage from the same direction. In these cases I would like once again to emphasize how important is the mechanical cleansing of the wound cavities and the surrounding tissue with soap and water, and how essential it is that the procedure previously described for cleansing the tissues should be undertaken in every case. The water must be sterile—boiled if necessary. The best soap to use is liquid green soap; ordinary soap, however, can be used in 0.25% carbolic, and such a solution, if made under unsuitable conditions, should be sterilized by boiling. All parts of the wound should be washed, including the actual site of fracture; and plenty of water should be used, so that mechanical removal of foreign bodies will take place at the same time. At the actual site of fracture the bone fragments must be washed very carefully, taking precautions against tearing any fragments of the periosteum. After long-continued cleansing in this way the whole wound is irrigated and washed carefully with normal saline. The wound is now re-examined and all the pockets and wound surfaces are irrigated with normal saline until they appear clean and the saline from the wound itself runs clear. As an example, in a splinter fracture with laceration the washing of the wound surfaces and the surrounding tissue should be continued for 10 to 15 minutes, and something like 5 litres of solution will be required for irrigation. This last procedure is not only valuable for the cleansing of the wound but makes the operation simpler and the recognition of damaged tissue easier.

It has been stated that these procedures are unsuitable because of the time involved for use in the front line. We would say that the additional use of the surgeons' time is adequately justified by the results, and in addition the actual operative procedure is rendered much quicker by the improved conditions. Another objection is the large quantity of sterile water, liquid soap, and salt solution required; and it is true that sometimes, with a large influx of such patients, this may present a serious problem. By adequate preparation beforehand such problems of supply can be overcome—on occasion sea-water has been used instead of saline with very good results; and all the difficulties and trouble are adequately compensated for by the improved condition of the patients. We believe that the application of this method is most valuable even in cases of gross infection; although it is obvious that one cannot sterilize gross infection by this means, it will wash out much foreign material, which will aid in the operative procedures, and remove the accumulation of pus and exudate. Indeed, in such cases it is often much more important, as only by so doing can one proceed to distinguish macroscopically between damaged and undamaged tissue. We do not mean to suggest that it is impossible to carry out the operation without this washing, but we maintain that it is made very much easier. We also feel that it is advisable after the operation to carry out irrigation again with saline before the application of sulphanilamide powder, to make sure that no tissue has been left which should have been removed. If additional incisions

have proved necessary for drainage, irrigation should be carried out through such an aperture as well. If the sides of the wound are gently wiped with soft gauze under the stream of saline it is surprising how much tissue and blood-clot are washed away which would normally be left in the wound cavity as necrotic material.

Operative Procedures for Severely Infected Wounds

In the previous world war the problem of gross sepsis in wounds was not solved, and even up to the end of that conflict most surgeons refrained from active surgical intervention in the presence of severe infection. Such wounds, and particularly gunshot fractures, are now being operated upon even after a long delay, and are treated in the same manner as we have described with recent ones. It appears that it is less dangerous to treat them in this way than to leave necrotic material in the wound to separate naturally. It was feared at first that damage to the defensive barrier which had been formed against infection would cause an increase of both the local sepsis and the general toxæmia. There is no doubt that the operative procedures described will remove this defensive area in many places and damage it in others, and will certainly introduce a large fresh wounded area where the struggle between the body defences and the bacterial infection will proceed; the operation will also often result in an increase in the toxæmia: all these things do in fact take place, but the increase in the general reaction has not proved serious, and the local condition has not deteriorated as might have been expected. The mechanical cleansing of the wound and the removal of dead tissue improve the defences of the body and the condition of the wound itself; and the surgical cleansing of the wound must be carried out most thoroughly—that is, on the completion of the operation all necrotic and infected tissue should have been removed. It would be ideal if all the excisions with the scalpel and scissors were made through undamaged tissue; this is rarely achieved in grossly infected wounds, particularly in the thigh, as in such cases the anatomical difficulties often render it impossible and the removal of fascial layers and large areas of muscle would make too great a sacrifice to warrant such a procedure. Under these conditions one must secure adequate drainage for the sepsis which cannot be removed surgically. We conclude that operative procedures can be undertaken with great advantage in cases of gunshot fracture of the thigh with gross sepsis. Excision of all infected or necrotic tissue should be undertaken if possible, adequate drainage must be established in either case, and sulphonamide preparations should be used both locally and orally; and, finally, complete immobilization of the limb should be procured by means of closed plaster.

We think that drainage is so important that details of the procedure are worthy of mention. There are three basic requirements: (1) incision and approach to the site of fracture from the lateral aspect of the thigh through the vastus lateralis muscle; (2) funnel-like excision of this muscle with the apex at the seat of the fracture; (3) suturing, if necessary, of the skin edges to the deep fascia.

I have previously suggested that the lateral aspect of the thigh is the site of election for the approach to the fracture, as it allows of adequate drainage, there are no large structures which impede one's approach, and it can be used throughout the length of the thigh from the trochanter to the external malleolus of the femur; only in cases of approach to the head or neck of the femur would it be necessary to extend the incision into the gluteal muscles. Only in exceptional circumstances, with wide destruction in the lower third of the femur, would the biceps femoris need to be incised. If the actual wound, either of exit or entrance, is on the lateral or the posterior aspect of the limb, it may be suitable for use as drainage without further incision. If the wound is not in this situation, then drainage must always be done from the lateral aspect. During the lateral approach great care should be taken at the actual site of the fracture, but drainage from the fracture site must be adequate, and small exposures are to be deprecated. This large exposure has the additional advantage of permitting adequate inspection. Muscle layers, however, adjoining the bone fragments must be carefully preserved at both ends, as the blood supply to the periosteum mostly passes through this site. Muscle must therefore never be

detached from the periosteum or from the ends of the fractured bone, and excision of muscle at this site must always be minimal. It is perhaps advisable at this stage to emphasize again that no periosteum should be removed; and even if some doubtful bone fragments insecurely attached to periosteum are taken away, the small, even minute, fragments of periosteum should be retained.

The object of suturing skin edges to deep fascia is to prevent premature closing of the wound cavity with consequent pocketing. The skin edges are sutured to suitable deep fascia, or often to muscle, by means of two or three catgut sutures on each side of the wound cavity. The elastic pull of the skin then tends to retract the deep muscle layer and thus prevent occlusion of the cavity deep in the limb. This suturing should not be undertaken until the wound has been amply treated with sulphanilamide powder. It is essential to prevent any infection under the skin flaps, and this is also guarded against by the use of catgut, which will absorb rapidly and enable the skin edges to retract later. This usually occurs in 7 to 12 days, during which time the success of the operation is being decided. This procedure also seems to reduce the depth of the wound and the depression of the scar afterwards.

Conclusions

I have described the aims and technique of the operations undertaken for gunshot fracture of the femur at various times after occurrence of the injury and with varied degrees of infection. It has been shown that when operation is undertaken within a short time the procedure is strictly confined to the removal of foreign material and damaged or devitalized tissue. In such cases additional drainage is seldom required, but the wounds should not be sutured. In treatment undertaken at a later time after the injury the method of choice is wide excision of infected and necrotic tissue and great care in mechanical cleansing, followed by free drainage.

I have concluded that adequate excision of muscle, so as to produce a funnel-shaped aperture for drainage, is of great importance. Adverse criticism has been expressed of this point of view. It is stated that this unnecessarily wide excision would cause an increase not only in the extent of muscle contracture but in the loss of power in the limb as a whole, and that it would increase the devitalization of the bone fragments with the risk of non-union of the fracture. I have never suggested that the excision should be excessively wide, and have pointed out the dangers of the removal of muscles with arteries traversing them; in consequence I have advocated the lateral approach through the vastus lateralis. In 350 cases of such fractures with gross sepsis upon which I operated I have not had one single case of non-union of the fracture. In addition, owing to the use of incision through the vastus lateralis and the technique of suturing the skin to the deep tissue, we have not seen defective movement of the limb as an after-result which can be attributed to post-operative defect in muscles.

I would like to remind readers that the first task in modern warfare in the treatment of a wounded man is to prevent the loss of the man's life and limb by infection. We believe that this is mainly achieved in the case of gunshot injuries of the thigh by the operative procedures described, prolonged immobilization in plaster, and the use of local and oral sulphonamide preparations. We admit that the procedures described are often tedious and time-consuming, and we have been told that such treatment cannot be used when the number of patients is large. We believe, however, that the methods described are irreplaceable by any other method of therapy, and by their means 95% of our patients with these injuries have their lives and limbs saved. Other methods, and splinting, though useful for transport, are unsuitable for immobilization treatment over any length of time and cannot replace the use of plaster. Inadequate excision and temporary splintings could only be justified under conditions of great stress, to enable the patient to be transported from the front line to hospital; we do not think that any considerations of time should weigh when the patient's life and the ultimate fate of the limb are at stake.

In view of the criticism that these procedures are prohibitively time-consuming I would like, in conclusion, to give an average estimate of the times which the various procedures take under our conditions.

The patient is put on the orthopaedic table, a spinal anaesthetic is given, the extension apparatus is applied, and the limb thoroughly washed. This work is mainly undertaken by one and the time required is approximately half an hour. The patient is helped by one assistant or an experienced sister, and a nurse attending to the instruments. If the knee-joint is opened and the wound has to be dealt with as described, the procedure would take approximately 24 to 25 minutes. The procedure involves the femur above the great trochanter, and partly into the hip-joint, the procedure will take from 40 to 60 minutes. If, however, the fracture is in any part of the shaft of the femur the work is easily completed in half an hour. The average length of this part of the operation is 30 minutes. The third part of the procedure—that is, the application of the plaster—is performed by trained nurses, usually two with a third for the bandages. The application of plaster, including a half-hour drying, takes 20 to 25 minutes, and 10 minutes is required for drying before the patient is moved. Thus three tables allow continuous flow of wounded. Each of these stages averages 30 minutes, and each patient therefore requires one and a half hours; but one patient is dealt with each half-hour, and in a 16-hour working day, with one hour for dinner, it is possible to attend to some 25 to 35 wounded men. This is the maximum but has been easily attainable under such a system. The team consists of 9 people, who work on three tables; there is one skilled surgeon in the team, and usually three experienced orderlies. In order that the work shall proceed continuously it is necessary to have another experienced doctor available for the sorting of the wounded as they arrive, directing for radiography or for other purposes as may be required, also choosing the next patient for operation. This same doctor could administer the spinal anaesthetics. This team is sufficient to deal with a large influx of wounded men, since there are a number of cases of femur fracture to 400 or 500 total wounded as a rule. Thus all the femur fractures among 1,500 wounded men can be treated in 3 days. Admittedly it is unwise to wait till the next day, but under conditions of stress this can be done successfully if the patient has been given sulphanilamide powder by mouth locally. We have found that in these conditions the proportion of dangerous infection is not higher than 2%. Up to 2% may show secondary haemorrhage, but in not more than 1% such cases is the haemorrhage likely to be dangerous. We can therefore, at least, say that 90% at least can be evacuated in excellent condition and the majority of these patients will have their wounds healed and the fracture consolidated before the first plaster needs renewal.

SOME THERAPEUTIC FALLACIES

BY

J. W. LINNELL, M.D., F.R.C.P.

Physician, Metropolitan Hospital; Consultant to the L.A. Hospital Service

AND

W. A. R. THOMSON, M.D.

First Assistant, Medical Unit, St. Thomas's Hospital
Physician, E.M.S.

A few years ago one of us had occasion to give a lecture in a London hospital to a number of general practitioners. In it he happened to question the value of the generally accepted forms of therapy, to be hotly attacked by a section of his hearers on the score that he was taking away their "treatment." It was in vain he protested that if this could be proved to be valueless it should be discarded. They were not to be pacified. Shortly after he had a similar experience in the Provinces. This owes its origin to these two incidents. It is not unexpected that all our conclusions will be accepted by readers. If they succeed in evoking a critical spirit alas! sadly lacking—in regard to present-day methods of treatment, we shall be content.

Essential Hypertension

The number of men and women in middle and late life who "suffer" from this condition is enormous. The number who are living full and vigorous lives in blissful ignorance of the fact that their blood pressures are abnormally immeasurably greater. Of those in the first category few have any symptoms referable to the condition if they have been informed by their doctors that they were ill.

complicated high blood pressure gives rise to no symptoms itself in the large majority of patients; few without knowledge of its presence complain of dizziness, a sense of fullness of the head, occipital headaches, and any others of the list of symptoms ascribed to it in textbooks of medicine. Such symptoms are nearly always due to an anxiety state largely dependent on knowledge of the height of their blood pressure.

Before criticizing the usual treatment of hypertension it is well to remember that its cause is quite unknown, even if numerable theories regarding it have been advanced at one time or another. In spite of common medical belief to the contrary, infections, whether general or local, auto-intoxication derived from the bowel, prolonged physical strain, and a high protein diet have, so far as is known, nothing to do with it. Nervous strain may raise it temporarily; there is no evidence that it can produce it. Endocrine disturbances are easy to name; they are harder to incriminate.

In view of these facts treatment must be unsatisfactory. It can be said at once that therapeutically we are powerless to reduce blood pressure save temporarily. Nevertheless, prolonged rest in bed, regular purgation, repeated venesections, and many descriptions, all manner of baths, scores of drugs and organic extracts, high-frequency currents, diathermy, and we know not what else are constantly being used by the over-enthusiastic therapist. The public also likes "treatment" and is willing to pay for it. In the present state of our knowledge is it not more logical for us to approach the question of treatment as philosophers? A patient who has been told that he has a high blood pressure often lives in constant dread of a "stroke." When why tell him when we discover it? If he has been told already, why not reassure him by telling him of people with blood pressure as high as or higher than his who are living full and active lives; that many of them will reach the allotted span; and that if we could bring down his blood pressure the chances are that he would feel the worse for it? In the case of his relatives, of course, the position is rather different, and they should be informed that the expectation of life is not so good as in an individual with normal or low blood pressure. So long as there are no complications the patient should not be allowed to consider himself an invalid; on the contrary, he should be urged to keep up his interests, though on general grounds he should be advised to avoid overstrain, both physical and mental. He should be encouraged to take moderate outdoor exercise: golf played in leisurely manner is—or, alas! was—he game *par excellence* for hypertensive patients. Often they sleep well. When there is insomnia sleep should be ensured by a nightly dose of a sedative, but no one should be initiated into the habit unnecessarily. He should be allowed an ordinary mixed diet, unless perchance he be obese, when his weight should, if possible, be brought down gradually to reasonable proportions by dieting. This last is a most important measure, for, one thing, there seems to be some connexion between obesity and hypertension; for another, it seems illogical to allow an already overworked left ventricle to be subjected to a further strain which is avoidable; and, for yet another, he raised diaphragm and its small range of movement present in obese people can only increase the heart's handicap. A hypertensive patient who has brought himself to submit to the loss of superfluous flesh is greatly gratified, as a rule, by the results of his abstinence.

Hypotension

Of recent years there has been an increasing tendency to diagnose a condition known as "low blood pressure." In consequence a new sword of Damocles has been hung over the heads of numbers of healthy people. A doctor, unable to find any organic cause for a patient's complaints, discovers in the course of his examination that he has a systolic blood pressure of something in the neighbourhood of 100 mm. Hg. He immediately fastens on this, with the result that a new invalid is created, to become almost inevitably the victim of polyvalent therapy.

Except in a very small and limited group of conditions such as shock, severe haemorrhage, coronary thrombosis, Addison's disease, and a severe infection such as influenza, hypotension is of no clinical significance. Our practice is, when we find a middle-aged man with such a blood pressure as we have mentioned and for which there is no apparent cause, to con-

gratulate him upon the state of it. Apart from aught else, such a man is almost certainly immune to hypertension.

Arteriosclerosis

For this there is no known treatment. Yet how much honest endeavour is wasted in striving to stay its progress and restore its ravages! Why pretend to achieve the impossible? Surely it is better to accept the inevitable. No useful purpose, however, is served by telling a patient that he has arteriosclerosis. That much can be done to help him and his relatives by advice and by the treatment of various symptoms as they arise is certain. Nevertheless, the chances are that he will profit most by encouragement.

Angina Pectoris

The number of drugs used to reduce the frequency of attacks of angina pectoris should alone make one suspicious of the efficacy of any of them. Evans and Hoyle (1933, 1934) in a fine piece of work tested a host of them—sodium nitrite, mannitol hexanitrate, erythrol tetranitrate, potassium iodide, luminal, chloral, morphine, papaverine, phenacetin, diuretin, euphyllin, belladonna, digitalis, lacarnol, and harmol—to find that none of them acted better than the placebo they used as a control. And yet there must be few of the thousands of victims of angina pectoris in this country who are not taking at least one of them regularly on the advice of their doctors.

Nitrites, particularly in the form of freshly prepared glyceryl tetranitrate tablets, dissolved rapidly in the mouth before being swallowed, are of inestimable value not only in cutting short individual attacks but also in preventing them if they are taken immediately before exposure to such conditions as are known by experience to be likely to induce them. So transitory is their effect, however, that to give them, say, three times a day—as is often done—to prevent attacks is even less reasonable, than to inject adrenaline three times a day to prevent attacks of asthma.

Cardiac Bruits: Simple Tachycardia

It would seem that to many practitioners the mere presence of a bruit is enough to warrant the administration of digitalis. The single indication for digitalis is heart failure in some degree, and this whether the bruit be or be not of organic origin.

Again, the mere presence of tachycardia seems still to many practitioners an indication for digitalis. It has no effect in simple tachycardia due to nervous, toxic (including thyrotoxic), and anaemic states. It is heart failure and not tachycardia which is the indication for digitalis.

Paroxysmal Tachycardia

An attack of paroxysmal tachycardia often arouses needless anxiety in patient and doctor alike, and recourse is straightaway had to a variety of drugs, including inevitably digitalis. The first thing is, naturally, to make an accurate diagnosis, for it is necessary to exclude an unusual degree of simple tachycardia, paroxysmal auricular fibrillation, and paroxysmal auricular flutter. An electrocardiogram taken during an attack is of great value, though not always essential. Paroxysms differ in origin and type and affect both healthy and diseased hearts. The treatment varies from type to type, and the prognosis from patient to patient, but there are a few valuable rules to keep in mind as regards both.

Sometimes the tachycardia is ventricular in origin. Here the prognosis is usually grave, as in the large majority of patients serious myocardial disease is present; most cases, indeed, follow an attack of coronary thrombosis. It is then vital to stop the paroxysm as soon as possible. Digitalis, however given, is almost certainly ineffective and in large doses may be positively harmful, whereas quinidine sulphate, whether given by mouth or intravenously, may produce some of the most dramatically beneficial results in medicine. Far more commonly the tachycardia is supraventricular in origin, either auricular or nodal. Here the prognosis is usually excellent, as in the large majority of cases the myocardium is healthy—it is, indeed, practically only in cases of very diminished cardiac reserve, whatever the cause, that the prognosis is doubtful. Paul White (1937) goes so far as to say that the condition is "usually unimportant." Unless the life of the patient is crippled through the frequency or the length of attacks, or the reserve of the heart is known to be already small, active treatment is

unnecessary. It is generally advisable for the patient to rest during an attack; otherwise, little is needed save strong reassurance as to its innocence. Moreover, a small percentage of patients can themselves stop an attack by pressing on the carotid sinus in the neck, holding the breath, inducing retching, adopting a certain posture, and so on. If it is deemed advisable or necessary to stop an attack on account of its long continuance a subcutaneous injection of acetyl-beta-methylcholine chloride is the procedure most likely to be successful, though it is one never to be hastily adopted, since its effects in other ways may be alarming. Digitalis neither stops paroxysms nor diminishes their incidence. Quinidine sulphate is reputed to do both occasionally, although this is not our experience.

As a toxic goitre is sometimes responsible for the disorder it is always wise to exclude its presence, since a subtotal thyroidectomy in such a case may be the means of dispensing with all other kinds of treatment.

Paroxysmal Auricular Fibrillation

Marvellous as is the effect of digitalis in most cases of established auricular fibrillation, it will not stop individual attacks of paroxysmal auricular fibrillation, nor is there any satisfactory evidence that its regular administration prevents such attacks. In themselves these are—contrary to general belief—usually surprisingly harmless, and there is, as a rule, no urgency to endeavour to stop one, as it may easily and spontaneously cease after a short time. If, however, it persists hour after hour to the great discomfort of the patient, or if the cardiac reserve is known to be small, and in any case if signs of congestive failure appear, it can usually be stopped by the oral administration of quinidine sulphate at frequent intervals. As one of the most fruitful causes of paroxysmal auricular fibrillation is thyrotoxicosis, and a subtotal thyroidectomy generally results in a complete cessation of attacks, in every case a goitre should be diligently searched for—even if mitral stenosis is present.

Shock

This is a result of vasomotor and not cardiac failure. Drugs such as digitalis and strophanthin, which are often administered, have therefore no place in its treatment. It should be remembered, too, that with a reduced volume of blood reaching the heart it is necessary for it to beat rapidly to maintain the circulation.

Bleeding

Calcium is widely used in the treatment of purpura, menorrhagia, haemoptysis, epistaxis, post-operative haemorrhage, and haemophilia. It is also often given before operation as a prophylactic against haemorrhage. Yet, according to Hunter (1938), there is no pharmacological evidence that it either increases the coagulability of the blood or shortens the bleeding time. In his opinion there is no justification for its use in such conditions as we have mentioned; and, as regards its use before operation, it is only of value in cases of obstructive jaundice, in which probably part of the existing blood calcium has become bound to the bile pigment and is thus unavailable for the process of coagulation. Even in these cases administration of vitamin K is more important.

Chilblains

The use of calcium salts in the treatment of chilblains and allied conditions is practically universal. Yet there are no sure grounds for its use. In all these conditions the serum calcium is normal.

Anaemia

Tens of thousands of people are treated for anaemia who are not anaemic. A clinical diagnosis of anaemia is apt to be fallacious. In the examination of any patient in whom anaemia is suspected an estimation of the haemoglobin should never be omitted. If anaemia is found to be present every endeavour should be made to discover its cause. This may be revealed in the course of a thorough clinical examination. Often a full examination of the blood is not only advisable but necessary.

Most cases of anaemia with a low colour index are benefited by iron if effective preparations are used in adequate dosage. It is, however, often discarded as useless after trial in perfectly proper cases simply because the dosage has been inadequate. In this connexion we consider the recent fashionable craze for

giving iron by injection deplorable. According to Witts (1930-1) the majority of ampoules of iron on sale contain infinitesimal amounts of the metal and are ineffective; the potent preparations cause much pain and occasionally iron poisoning. Vaughan's (1932) dictum that intravenous, intramuscular, and all proprietary preparations of iron are as useless as they are expensive is practically true.

Again, liver is not a panacea for every type of anaemia. It is, with rare exceptions, only of value in the treatment of pernicious anaemia and other megalocytic anaemias. As regards the method of its administration, on all grounds—cost, comfort, convenience, and effectiveness—parenteral therapy is infinitely preferable to oral; indeed, the latter method should now be considered archaic save in a few cases. Much has been written on the necessity for giving dilute hydrochloric acid as well as liver. It seldom relieves any accompanying indigestion; it has no effect on the anaemia.

Finally, there is no evidence that arsenic is of any value in the treatment of either microcytic or megalocytic anaemia.

Toxic Goitre

The truth of Joll's (1932) statement that subtotal thyroidectomy is "the method which most rapidly, most certainly and most safely restores the patient to a state of economic efficiency and involves least likelihood of danger of relapse" is now firmly established. Iodine does not cure. This truth cannot be stressed too strongly. In most cases, for reason not yet understood, it ameliorates the signs and symptoms, but only temporarily. Its administration for a short period before and immediately after operation has contributed not a little towards the extraordinary safety which now attends subtotal thyroidectomy when conducted by a team of experts. In our opinion its use should be restricted to these periods. The common practice of giving it for months and even years to end in the belief that it cures is strongly to be condemned. Thereby operation is often postponed till cardiac complications, extreme emaciation, or a psychosis supervenes.

The Common Cold and Influenza

The clamant demand of the layman for a cure of these, the banes of his life, would appear to have had such an undesirable effect on our profession that we feel it our duty to insist on the uselessness of preventive inoculation. In spite of the many large-scale investigations that have been carried out, not one of which has shown that any benefit accrues from such treatment, uncritical impressions still hold the field, and numberless patients are subjected year after year to prophylactic courses of vaccines.

Another point: sulphonamide compounds have no action on filter-passing viruses. It is unwise, therefore, to give them to patients suffering from uncomplicated colds and influenza. Moreover, to quote Beaumont and Dodds (1941), "the prophylactic administration of small doses of sulphanilamide against various types of infection, such as sore throats or colds, is useless."

Bronchitis

A diagnosis of bronchitis, whether acute or chronic, means almost invariably the prescription of an expectorant. The number of gallons of expectorant mixtures used in this country alone in any one year is enormous. That their action is beneficial is taken for granted. Yet it is doubtful if they do not do more harm than good. It seems not only a clumsy but a harmful procedure to try to increase bronchial secretion by irritating the vagal nerve endings in the delicate mucous membrane of the stomach through the administration of such nauseating doses of emetics. Nevertheless, this is how such expectorants as ipecacuanha, ammonium carbonate, and squill act—if they do act effectively when used in pharmacopoeial doses, which is not certain. The chances are that they do little more than cause gastritis. It may be said that this accusation cannot be brought against the iodides. Their action, however, has been found to be very variable, and is probably dependent on the sensitiveness of the individual patient to iodine. What is urgently needed, of course, is a complete reconsideration of the whole subject of expectorants. Unfortunately, as Clai (1937) says, the pharmacology of cough has scarcely advanced at all in the last half-century. We, for our part, have practical

SOME THERAPEUTIC FALLACIES

Nov. 6, 1943

even up expectorants in the treatment of bronchitis. In acute bronchitis—a condition which tends to spontaneous cure—we rely chiefly on rest in bed, an abundance of hot drinks, steam inhalations, and sedatives to control an irritating cough; in chronic bronchitis, on general measures as they affect physical condition, climate, environment, occupation, etc., and, since chronic bronchitis of any standing inevitably connotes bronchiectasis, we advise such patients as seem capable of it to practise postural drainage every morning and at intervals stretching himself across a bed or couch with the trunk hanging steeply over the side and coughing till no more sputum is produced.

Lobar Pneumonia: Bronchopneumonia

In spite of the amazing success of sulphapyridine (M & B 693) and allied preparations in this disease there is still need for the well-established non-specific methods of treatment: measures to achieve rest and sleep, good nursing, a sufficiency of fluids, and oxygen. Special attention has always been directed towards the heart. Most doctors seem to visualize a heart poisoned by infection gradually dilating as it becomes flabbier till in the end it fails. Yet seldom, even in fatal cases, are the classical signs of congestive heart failure seen. More over, in a radiological study of 119 hearts in pneumonia was witnessed in no more than three. It is not cardiac failure which is to be feared; it is peripheral circulatory failure. This is due to loss of contractility of the muscular coat of the peripheral arterioles, with consequent stasis of the blood in the capillaries.

If this be the case, the uselessness of so-called "heart tonics" is manifest, even if they can ever be proved to have any stimulating effect on the myocardium. Certainly alcohol, whatever its value as a food or a sedative, has no such action, nor have strychnine and camphor, while strychnine does not appear to exert any effect on the poisoned peripheral vessels. Digitalis—in popular medical opinion the most potent of all "heart tonics"—is, after all, a poison, and its beneficial effects must be very convincing to warrant the further poisoning of an already poisoned organ. As a matter of fact, its effect in lobar pneumonia has been carefully investigated by many workers, among whom Wyckoff, DuBois, and Woodruff (1930) concluded that its routine use was dangerous and in large doses increased the mortality; while Cohn and Lewis (1935) in an analysis of 1,456 cases found that it did not influence the course of events. Whatever be the value of expectorants under any circumstances, they should logically have little place in the treatment of lobar pneumonia unless there is an associated bronchitis, for most of the exudate is absorbed and not expectorated.

All we have said about the heart, the circulation, heart tonics, etc., in lobar pneumonia holds also in bronchopneumonia. The value of such preparations as sulphapyridine in the individual case is, however, much more a matter of trial and error. Success or failure probably depends on the extent to which the pneumococcus is responsible for the infection, and this is difficult to assess.

Constipation

Incredible quantities of purgatives are ordered daily by doctors, in most cases needlessly and ignorantly a marvellous first place to treat roughly and ignorantly a marvellous piece of mechanism like the intestinal canal, with its delicate epithelium, its wonderful secretory and absorptive apparatus, and its beautifully balanced rhythmic movements, is little less than an outrage. There is an ingrained belief in doctors and patients alike that manifold evils will result if the bowels are not opened once at least every twenty-four hours. Yet, as Gee insisted many years ago, this is not a natural law, and many people feel in better health when the bowels act once in every two or three days. There is little or no evidence to support the widely held opinion that auto-intoxication results from simple constipation: faeces are, after all, meant to dry in the distal colon, and toxic absorption is far more likely to derive from fluid faeces than from dry scybala. To quote Witts (1937): "Apart from mechanical distension, a constipated stool exerts little more influence on the patient in the colon than in the bed-pan." Again, in many people who complain

of constipation the faeces arrive normally at the pelvic colon, but subsequent evacuation is not adequately performed owing to loss of the conditioned defaecation reflex, generally caused by continued neglect to respond at once to the call to stool. It is, however, in the constipation met with in acute infections that purgatives may be definitely dangerous. Here constipation is chiefly due to dehydration, and to dehydrate further an already dehydrated patient seems hardly logical. Once more, though there has been of late a change of mind on the part of most surgeons as regards the preparation of patients for operation, the practice of preliminary purgation in all cases still obtains in some quarters. To dehydrate deliberately before operation and to use all kinds of ingenious means to rehydrate immediately after would seem to be the acme of illogical thinking.

We ourselves have less and less recourse to purgatives the years. Much can be done by stressing the harmlessness of constipation. "The ill effects of constipation are almost entirely psychogenic and due to worry over disturbance of habit" (Witts, 1937), and anxiety about the action of the bowel is probably in itself a fruitful cause of constipation. Much again, can be done by insistence on the necessity for cultivating a regular habit, diet, exercise, the provision of a low lavatory seat or the adoption of a squatting posture for defaecation, and the lubricant, liquid paraffin. There is seldom any urgency to open the bowels in acute infections under four or five days, and then this should be done by enemata and not by purgation. Enemata are almost certainly not used enough in the treatment of chronic constipation; a regular habit can often be regained by their daily use in constantly decreasing amounts.

Our thanks are due to Drs. John Parkinson, Donald Hunter, Hugh Dunlop, and Clifford Hoyle for their helpful criticism of various points we have tried to make in this very incomplete and discursive paper.

OBSERVATIONS ON THE ACID HAEMATIN METHOD FOR THE ESTIMATION OF HAEMOGLOBIN

BY

C. A. ASHFORD, M.A., Ph.D.

(From the Department of Physiology, University of Bristol)

The acid haematin (Sahli) method is one which is widely used for the estimation of haemoglobin, and is recommended (M.R.C. Report, 1943) for use when the Haldane method cannot be employed. Though not ideal, it has several points in its favour—e.g., the reagents are simple and independent of a supply of CO, and the colour obtained with 20 c.mm. of blood is strong enough to read easily in the Haldane type of haemoglobinometer tube. While the conversion to alkaline haematin has many advantages (Clegg and King, 1942) the colour produced in similar concentrations is much weaker, and consequently comparison, particularly visual, is more difficult. A serious disadvantage of the acid haematin method, however, is that the fluid is a suspension and not a true solution (Barcroft, 1928). Considerable sedimentation has usually been observed in 24 hours at room temperature in several hundred samples investigated in this department. Moreover, occasional samples of blood give suspensions of such turbidity that they are impossible to read.

A further disadvantage is the confusion which exists regarding the length of time necessary for colour development. This lack of uniformity is illustrated by the following examples: Myers (1924) and Beaumont and Dodds (1941) give 2 hours as the time necessary at room temperature, while Whitby and Britton (1939) give 30 to 40 minutes. Stewart and Dunlop (1937) say: "Compare after 2 minutes," while the University of Glasgow Standing Committee (1940), as in the original Sahli (1909) technique, recommend comparison after one minute. Smith (1941) considered 10 minutes a suitable time for clinical purposes, and Campbell (1942) reported agreement with the Haldane method by comparing after 7 or 8 minutes. No doubt other workers use different times. These and other points were commented upon briefly by Ashford (1942). Since complete colour development undoubtedly requires time, it follows that divergent findings must result from the use of different times before comparison with a permanent standard. The time would, of course, be immaterial if a sample of blood of known Hb content was similarly treated at the same moment as the unknown. When, however, a standard such as the Newcomer disk (1919) is used the result will be inaccurate unless comparison is made at the time for which it has been calibrated by the makers. It would appear that this instruction has not always been supplied, or, if it has, has been neglected by the user. It would be advantageous to have agreed uniform conditions, and certain recommendations in that direction are made in this communication.

The Time Relations of Colour Development

A. At Room Temperature.—In the following experiments a Hellige colorimeter was used, and the "standard" was either a coloured glass of the Newcomer type or, more usually, a solution of acid haematin made up some 18 to 24 hours previously and filtered before use if not absolutely clear. A stop-watch was started at the moment when the sample of blood (20 c.mm. or a proportionate amount) was delivered into 5 ml. of N/10 HCl and mixed. The standard being already in position, the fluid was transferred to the vacant cup of the instrument and readings taken as rapidly as possible. The temperature was that of the room (14° to 15° C.). In these and in many other observations no increase of colour was observed after 2 hours, and this value was accordingly adopted as "100%" and the intermediate figures calculated as fractions of it. A typical curve obtained with normal fresh human blood is reproduced (see Graph).

Graph showing rate of colour development at room temperature.
Fresh human blood.

It will be seen that the colour development is initially very rapid, reaching 75% in 1 minute and 88% in 5 minutes. Essentially the same kind of curve was obtained in a number of experiments with ox blood. (In a few experiments it has been noticed that the rate of alkaline haematin formation at room temperature is very much slower in ox than in human blood.)

Comment.—The rate is somewhat slower than that reported by Newcomer (1919), and it is presumed that his room temperature (not stated) must have been higher than those obtaining in this laboratory. Plesch (1941) claimed 88% colour development in 2 minutes; this is higher than either of our figures. It follows that if a solution is compared at 15 minutes against a standard calibrated for 5 minutes the result will be 4 to 6% too high, and after 2 hours some 12% too high. Moreover, owing to the varying time (50 seconds to 2 minutes in a series of observations) necessary to make dilution and comparison when using the simple haemoglobinometer technique, the time for reading should not be less than 20 minutes at room temperature, and the colour would then be only 95% of the final

(2-hour) development. It is difficult to see how times of 1 or 2 minutes can be employed with accuracy, owing to the rapidity of the increase of colour in the early stages. To obviate the delay and to obtain complete colour development in a shorter time the effect of temperature was studied.

B. Experiments at 40° and 100° C.—It was not practicable to maintain the stage of the colorimeter at 40° to 45° C. or higher. The samples were therefore usually measured into tubes containing the acid and fitted with air-condensers to prevent evaporation. The were immersed in the water-bath for the time shown in Table I, I

TABLE I.—Rate of Colour Development at Different Temperature
(The Figures are the Readings in mm. of the Colorimeter Scale, the "Standard" being Constant in Each Experiment)

Species	Temperature °C.	Time t	Reading at Time t (R _t)	Reading after 5 min. at 100° C. (R ₁₀₀)	Ratio $\frac{R_t}{R_{100}}$

which two examples of results obtained with human and ox blood are given. Table II similarly reports an example of the course of the reaction at 40° to 45° C. The tubes were rapidly cooled melting ice before making the comparison. In all experiments sample measured with the same pipettes was allowed to stand 1

TABLE II.—The Rate of Colour Development at 40° to 45° C.
Ox Blood. (Readings of the Colorimeter Scale in mm.)

Temperature °C.	Time t	Reading at Time t (R _t)	% of Final Reading	Reading after 5 min. at 100° C. (R ₁₀₀)	Ratio $\frac{R_t}{R_{100}}$
Room	2 hours	29.92	100.0	23.3	1.28
42-45	5 min.	30.30	98.0		
	10 "	30.25	98.5		
	15 "	30.10	99.3		
	20 "	29.90	100.0	23.9	1.25
	5 "	30.60	97.6		
40-42	10 "	30.40	98.4		
	15 "	30.10	99.3		
	20 "	29.90	100.0	23.8	1.25
	5 "	30.60	97.6		

at least 2 hours at room temperature, and this value was used as the final, or 100%, figure. It thus appears that incubation in water-bath at 40° to 45° C. for 10 to 15 minutes gives results very close to that figure. As this was in a large volume of fluid in which the attainment of the raised temperature would be slower, there is little doubt that under the usual conditions of the estimation, where 20 c.mm. of blood is delivered into less than 1 ml. of acid, the reaction is at least 99% complete in 10 minutes. This technique has been adopted, with satisfactory results, for many rapid determinations in this laboratory. When the tubes fitted with condensers were immersed in a boiling-water bath for 5 minutes and cooled melting ice before reading, an increase of colour of about 25% was observed. This is indicated in Tables I and II by the ratio R_t/R₁₀₀ since the concentrations are inversely proportional to the colorimeter readings, the standard being at the same mark throughout each individual experiment. It was found also that this increased colour production was complete in 3 to 4 minutes. This finding is a further reason for the standardization of conditions and calibrations. It also conflicts with the statement of Berman (1919) that boiling for one minute over a free flame gives the same degree of colour as 15 minutes at room temperature. As the fluid obtained at 100° C. often rather turbid it is not suitable for use as a routine procedure.

Choice of a Standard

There is no doubt that for occasional routine estimation a permanent standard of the Newcomer glass type, properly calibrated and used under standard conditions, is the method of choice. Moreover, the tube employed should be rectangular in shape, since the standard has a plane surface; and it is an advantage if two pieces of glass, between which the unknown is placed, are employed. Furthermore, the tube should be graduated in terms of g. Hb per 100 ml. (or the Haldane scale) owing to the varying meanings which may be attached to the expression "100% Sahli" (see Ashford, 1942).

When a large number of estimations are to be made and a glass standard suitable for use in a colorimeter is not available, it is preferable to use a standard of blood of known Hb content similarly treated with acid. The standard made by dilution from a stock 3% solution of acid haematin (Cohen and Smith, 1919) has not been found entirely satisfactory, being usually more turbid than the fluid from a fresh blood, and the turbidity tends to increase with the age of the strong solution. As this is a thick suspension it is unlikely that the state of dispersion of the solution diluted from it would be identical with that of a freshly made suspension. The procedure therefore adopted was to prepare the acid haematin standard by appropriate dilution with N/10 HCl, from ox or human blood whose oxygen capacity had been determined when fresh by the Barcroft method, and which had been stored in the refrigerator, just before starting to draw the series of blood samples. This technique is justified by the observation that the rate of formation of acid haematin was unaffected by the storage of the blood, at any rate up to 2 weeks.

It has been further shown that it is permissible to use ox blood as standard when human blood is under test. Palmer (1918) stated that this was not so; but Cohen and Smith, who studied several species, did not agree with him. An example of our experiments is shown in Table III. It will be seen that

the ratios calculated from oxygen capacity and by comparison after conversion to acid haematin are very similar. The experiments have included "normal" and weaker samples of blood; none have been made in the presence of abnormal pigments—e.g., COHb or MetHb.

Discussion

The disadvantages of the acid haematin method have been summarized by Clegg and King (1942). Wu (1922) showed that the colour obtained depended on the plasma proteins, but concluded that in all normal samples variations in protein and lipid content were insufficient to cause an error. In fact, his figures showed that the amount of plasma could be increased 3 or 4 times above the normal ratio without causing an appreciable change, though there was a 20% deficit in colour when plasma-free Hb was used. His results were obtained with sheep's blood; if applicable to human blood they would suggest that the method can be used accurately over a wide range of anaemic bloods (cf. Table III). Nevertheless Wu favoured the conversion to alkaline haematin because abnormal pigments such as COHb, MetHb, and CyanHb gave a depth of colour in acid up to 15% above that of HbO₂. It does not appear likely, however, that the amounts of these pigments which may be present in human blood would appreciably affect the colour.

Summary

Formation of acid haematin from ox and human whole blood reaches completion at room temperature (14° to 18° C.) in 2 hours; the same depth of colour is obtained in 10 to 15 minutes at 40° to 45° C. The latter procedure is recommended for routine technique, and the permanent standard should be calibrated accordingly.

Heating at 100° C. for 4 to 5 minutes causes an increase of some 2% in colour. Boiling should therefore be avoided.

A standard obtained by dilution from a 3% stock solution of acid haematin was not found satisfactory. An alternative procedure is suggested.

Ox blood can be used as standard when human blood is being assayed.

My thanks are due to Prof. R. J. Brocklehurst for his interest in this work.

LOCAL APPLICATION OF SULPHANILAMIDE POWDER IN RADIOTHERAPY

BY

ALEXANDER A. CHARTERIS, M.B., Ch.B.,
D.P.H., F.R.F.P.S.

Radium Therapist and Donald Research Scholar for Cancer,
Western Infirmary, Glasgow

Sepsis presents a constantly recurring problem in radiotherapy, and its prevention or treatment merits the most careful consideration. Descriptions have previously been given of the antiseptic action of certain acridine compounds, and the success of proflavine in radiotherapy has been stressed (Charteris, 1937; Young and Charteris, 1940). In view of the increasing interest in local application of this substance, it is gratifying to find that my early estimate of its efficacy remains unchanged, and that its proper use makes various radiotherapeutic procedures possible and safe. This is especially true as regards superficial ulcerating growths, also tumours in the nose and its accessory sinuses, and in the realm of gynaecology. I have used proflavine oleate 1% in liquid paraffin, and the original preparation has been improved by the addition of enough oleic acid to produce complete solution.

There is a further important field for antiseptics, however, in the form of powder preparations where the parts must be kept dry, and this refers particularly to the after-treatment of patients, in contrast to their preparation and actual irradiation, when proflavine in an oily vehicle is usually excellent. For dry applications sterile sulphanilamide powder was chosen. It has been used in a large number of cases since early in 1942, and proved most satisfactory. There are three main kinds of application.

Methods of Application

The first and most general of these is in the care of unbroken skin undergoing a dry reaction after radiotherapy. If moist desquamation is to be avoided the skin must be protected against friction and pressure, besides being kept clean and dry. For the latter purpose powder dressings are excellent, and not only is sulphanilamide powder suitable in this sense but it also eliminates the risk of chronic pustules forming. A special use is found in the case of reactions about the vulva or anus, or in any place where apposition of the parts makes a more severe reaction likely, apart from any local variation in tissue sensitivity: regularly changed dry applications on gauze will at least limit desquamation in such situations if carried out two or three times in the day, according to circumstances.

Where it has been necessary to subject skin to something approaching maximal irradiation in order to deliver an adequate "tumour dose," moist desquamation is inevitable, and its treatment presents the dual problem of minimizing discomfort and diminishing post-radiational stigmata so far as is possible.

Bland oily dressings of some sort, or even tannic acid preparations, are much used, but I should now prefer dry sulph-anilamide powder from both standpoints. Its direct application is obviously impracticable; but the affected part is first covered with moistened protective gauze tissue, which is allowed to dry in position, and the powder is then dusted on. Dressings can be carried out as often as necessary without disturbing the protective layer, much after the style of some skin-grafting procedures. The outer surface can be gently washed, dabbed dry, and again dusted from time to time, the whole being covered by gamgee and a bandage.

Finally, there is the case of a superficial tumour with ulceration. Where some form of radium therapy is called for, the use of proflavine oleate as described will usually permit treatment to be carried through for at least a week without change of dressings. Sulphanilamide powder becomes useful, however, after irradiation is concluded, both to control sepsis and to limit reaction by keeping the part as dry as possible. Liberal application under a plain dry dressing is excellent, and changes are as a rule only necessary every three or four days, which is a consideration in a busy out-patient clinic. The absence of purulent discharge is often remarkable, in contrast to what is seen with some other forms of antiseptic treatment. When a small unbroken neoplasm is treated its surface will become a temporary ulcer owing to regression even when surrounding normal skin is unaffected by moist reaction, and the powder method is very helpful here. Its adoption immediately after treatment is finished usually results in a clean dry protective scab over the actual lesion, and on the face no dressing may be needed. This scab falls off, leaving a healthy patch of skin with little evidence of what was previously present. At a later stage, when all reaction has died away, any irradiated skin is often somewhat dry; there is no objection then to the use of a simple lubricant like lanolin or vaseline.

It is appreciated that the subject of antiseptics in radiotherapy is a large one, and that many different substances may prove helpful, but these notes are given in the hope that they may be of some practical benefit, since my own experience has led to the regular employment of the methods in my department.

I have pleasure in acknowledging once more Prof. C. H. Browning's helpful suggestions on the use of antiseptics.

THE RENAL FUNCTION IN MYXOEDEMA

BY

G. E. BEAUMONT, D.M., F.R.C.P.

Physician to the Middlesex Hospital

AND

J. D. ROBERTSON, M.D., D.Sc., D.P.H.

(From the Wards and Courtauld Institute of Biochemistry, Middlesex Hospital)

Means (1937) has stated that, except for albuminuria, the picture of nephritis is absent in myxoedema. Recently we (Beaumont and Robertson, 1943) described a case of pituitary hypothyroidism in which renal impairment was a marked feature, and we suggested that part of these renal signs might be due to the hypothyroidism. In the present paper seven cases of myxoedema have been studied. The findings are given in the accompanying Table. The second series of observations ("after thyroid therapy") were made three months after treatment was instituted, when the basal metabolism was constant on a maintenance dose of thyroid. In determining the basal metabolism the standards of Aub and DuBois (1917) were employed. The urea clearance of Möller, McIntosh, and van Slyke (1928) was confined to the maximum clearance in view of the errors consequent upon low urine output—i.e., all the tests were made during a diuresis. In carrying out the test of water excretion (dilution test) the subject drank a litre of water in a quarter of an hour, and the urine was collected over the next three hours. A series of five normal healthy subjects gave urine outputs of 840, 970, 1,370, 1,000, 920 c.cm.

with a mean of 1,000 c.cm. The urine concentration test was carried out according to the instructions of Fishberg (1939) a urine concentration of over 1024 is considered normal.

A study of the results in the Table shows that the ure clearance in myxoedema is low and rises significantly after adequate thyroid therapy ($t=6.05$; $P<0.001$). Of the case of treated myxoedema only one (Case 5) had a urea clearance within the range of Addis's normals (1917), and this was when she was still myxoedematous. It would appear that although thyroid medication improves the urea clearance, remains subnormal.

Table of Findings Before and After Thyroid Therapy

Case	Basal Metabolism		Urea Clearance (per cent. of Normal)		Urine Output (c.cm.) 3 hrs. after Drinking 1,000 c.cm. Water		Highest Specific Gravity Urine	
	Before	After	Before	After	Before	After	Before	After
1	-41	-1	49	85	800	1,230	1025	1021
2	-31	+8	38	56	660	815	1026	1021
3	-32	0	56	71	1,070	970	1026	1012
4	-32	-2	48	56	672	1,094	1025	1018
5	-37	-9	100	118	1,310	1,360	1027	1014
6	-33	-3	50	75	795	1,310	1021	1018
7	-42	+4	56	78	1,330	1,175	1024	1019
Mean	-35	0	57	77	948	1,136	1025	1018

The water excretion is normal in myxoedema, and after treatment with thyroid no significant change occurs ($t=1.98$ $P=0.1$).

Patients with myxoedema are able to concentrate urine as efficiently as normal people. Treatment with thyroid produces a significant change in the ability to concentrate urine ($t=3.55$ $P<0.01$). As these observations were carried out at least six months after treatment was instituted, and when the basal metabolism was steady, the low specific gravity herein reported does not appear to be due to the diuretic action of thyroid which is a feature when treatment is first begun.

No other evidence of renal impairment was found despite chemical and microscopical examinations of the urine. Albuminuria was not detected in any case.

Summary

The renal function of 7 cases of myxoedema has been studied before and after adequate thyroid therapy.

The urea clearance is diminished and rises after thyroid therapy. The urea clearance in treated myxoedema, however, still remains below normal.

The other tests of renal function, such as the water excretion and urine concentration, were normal.

Principles for the prescription of quinine in Germany (*Deutscher Arztblatt*, Nov. 1, 1942, 72) include the following: (1) Quinine must not be used as a prophylactic against influenza. (2) It is not to be used as an analgesic or tonic. (3) In the treatment of cardiac arrhythmia, and especially auricular fibrillation, quinine should be used so far as possible in the place of quinine. (4) The use of quinine as an "ecbolic" in midwifery can be continued. (5) So far as is necessary quinine can still be used besides the synthetic remedies for the treatment of malaria. (6) For the treatment of chills and influenza quinine is indispensable. There is no objection to the use of small quinine doses occasionally in influenza, in combination with ascorbic acid. (7) For the treatment of croup and bronchopneumonia (also whooping-cough) the injectable quinine preparations can be replaced by the sulphonamides. Only therefore, in isolated cases should bronchopneumonia be treated with quinine—for example, after operations or in whooping-cough. (8) In suppurating bronchitis and bronchiectasis the injectable quinine preparations are almost always replaced by guaiacol preparation or camphor in oil. Nevertheless, injectable quinine preparations can be used in isolated cases. (9) The use of quinine in sepsis, typhoid, and other general infections is now out of date and can be replaced by amidopyrine.

Medical Memoranda

Acute Dilatation of the Stomach

A case of this dangerous malady has just occurred in my hospital practice, and may prove of interest with reference to the article by Messrs. Lee and Somerville (1941) and the letter by Dr. Gustav Singer (1941), both in your columns.

CASE HISTORY

An otherwise healthy man aged 35 was admitted for pain in the abdomen, vomiting, and constipation. Examination showed marked meteorism, tenderness in the lower abdomen, and a ballooned rectum with fullness in the upper part of the recto-vesical space. Two enemata were without result. Then a spinal anaesthetic was given and a rectal tube passed, but without effect. The abdomen was opened by a right paramedian incision, and a volvulus of the sigmoid colon was reduced easily, by hand, within the abdomen. The tube was guided up into the descending colon, and gas and some faecal matter were passed on the table. The sigmoid colon which was very mobile, was stitched to the lateral parietal peritoneum with two catgut sutures passed through one of the longitudinal muscle bands. One stitch fixed the colon to the abdominal wall above the iliac crest, and the second attached it to the peritoneum just above the external iliac vessels. It was difficult to place more sutures because of the distension, and the bowel remained in good position. After a gentle general routine exploration the abdomen was closed in layers, with the addition of three tension sutures passing through all of them. The operation took 55 minutes, and the patient left the theatre in very good condition.

Morphine gr. 1/4 was given some hours later, during the night, and the patient drank some glucose water. There was no nausea or vomiting. Twenty-four hours later there was still constipation, distension was much increased, and there was pain in the epigastrium with slight hiccup. Enemata, intravenous pituitrin, flatus tube, and eserine failed to have any effect; the pulse was slightly accelerated.

Fearing acute dilatation of the stomach, I passed a Ryle's stomach-tube and applied a syringe. About five pints of the typical pea-water contents was withdrawn. This was run into the rectum slowly, but most of it was rejected. Auscultation of the abdomen revealed faint peristaltic noises, but, as constipation was persistent and pain and distension increasing I prepared to operate. As a last conservative measure, however, morphine and a spinal anaesthetic were given, and the patient was turned on his face in the Trendelenburg position. Within a few minutes a large loose fluid motion was passed with much flatus. He was returned to bed, and in the morning there was no distension and his condition was quite satisfactory. Except for slight wound sepsis he made a perfect recovery.

COMMENT

There seems still to be a lack of uniformity of opinion as to the pathogenesis of acute dilatation of the stomach. From the above case it appears to me that Rokitsky's theory cannot, in all cases, represent the initial cause, for the patient was lying on his side with the foot of the bed raised when the symptoms began, and the dilatation of the stomach appeared as a sequel to the lower abdominal meteorism.

I suggest that there was interference with the normal co-ordinated action of sympathetic and parasympathetic nerves controlling the stomach and bowel, brought about either by toxæmia or by trauma; that is to say, a fault of neurogenic origin. This resulted in an overaction of the gastric secretory function and in non-relaxation of the lower bowel sphincters. The eserine failed to stimulate the parasympathetic nerves to the large bowel sufficiently to cause relaxation of the sphincters and evacuation, perhaps because it was given in too small a dose, and the incoordination was relieved only by the spinal anaesthetic, which, while causing a temporary paresis of the lower spinal nerves generally, also inhibited sympathetic efferent impulses which passed in the sacral nerves to the presacral plexus and which caused contraction of the lower bowel sphincters.

Acute dilatation of the stomach therefore appears to me to be a manifestation of a general tendency to a sympathetico-tonic state or to incoordinated overaction of the sympathetic, and in future cases I shall consider the use of spinal anaesthesia in the treatment of this condition as well as the usual methods of posture and gastric aspiration.

I think that I made the error, in this case, of not leaving the flatus tube high in the descending colon, for adequate drainage of the bowel might thereby have been facilitated and the gastric complication have been avoided.

R. D. MACRAE, M.B., F.R.C.S.Ed.,
Lieut.-Colonel, I.M.S.

X-ray Diagnosis in Pulmonary Tuberculosis

The following case record may be of interest to many readers in view of the prominence given to mass radiography of the thorax.

CASE HISTORY

A single woman aged 40, a cardboard-box maker, was admitted to this hospital on Dec. 16, 1942, in a state of confusion with much restlessness and agitation. She was very resistive to attention in all forms. Physically she was an extremely poor specimen; her weight on admission was only 4 st. 4 lb., and her height scarcely 5 ft. The thorax was very narrow and the chest mechanism poor, giving a small tidal-air content. The breath sounds were rather harsh and there was a slight dullness towards the right base. She had a definite enlargement of the thyroid gland.

Blood examination showed: red cells, 4,200,000 per c.mm.; Hb, 80%; colour index, 0.95; white cells, 3,100 per c.mm.—lymphocytes 57% (1,767 per c.mm.), polymorphonuclears 43% (1,333 per c.mm.); halo reading, 4.7%. The blood sedimentation rate was: 1 hour, 29 mm.; 2 hours, 65 mm.; 4 hours, 78 mm. Blood Wassermann: \pm 3 M.H.D., — 5 M.H.D. Examination of the cerebrospinal fluid resulted as follows: Wassermann test, negative; gold colloidal test, negative; protein, 30 mg. per 100 c.cm.; cell count, 3.3 per c.mm. Urine examination showed a normal specimen.

The sputum could not be examined, as no cough or expectoration was present. The faeces, however, were tested for tubercle bacilli, but a negative result was obtained. The temperature chart was quite atypical.

From a radiograph taken Jan. 26, 1943, the lungs seemed then to be quite clear. It was assumed, however, that there was a tuberculous focus somewhere in the lungs, and she was treated accordingly. At intervals she refused food, and in spite of all possible care and attention she died on April 16, 1943.

A post-mortem examination showed extensive infiltration and part coagulation of the middle and lower lobes of the right lung. Apart from an enlarged and cystic right lobe of the thyroid all other organs were in a fairly good condition, confirmed by histological examination.

SIGNIFICANCE OF THE THYROID

The thyroid activity was determined by estimating the iodine elimination by the urinary route. This gave almost 1 mg. excreted as iodine during 24 hours. About one month later a similar estimation was carried out, 0.61 mg. of iodine being recovered. Both of these figures are much in excess of normal. The fall in iodine excreted in the second instance was accompanied by a further loss in weight. Increasing mental and physical deterioration was also manifest at this period.

The thyroid gland was examined for iodine after the necropsy. The figure found was below normal. This is to be expected when the general pathology of the case is taken into account. Concurrent exhaustion of the gland would now be in progress. Histologically there was much evidence of past activity—more so in the left lobe. The right lobe showed marked fibrous degeneration. The history of the case revealed that the enlargement of the thyroid was first noticed about fifteen years ago. The whole gland weighed 54.86 g. This would indicate scarcely 50% increase.

COMMENT

In view of the above findings it is possible that the thyroid activity may have been a factor in accelerating or aggravating the tuberculous process in the lung to a rapidly fatal termination. There is no doubt that hyperactivity of the thyroid would cause increased pressure on an already strained metabolism.

Although the B.S.R., the leucopenia, and the slight dullness around the base of the right lung were individually not diagnostic of pulmonary tuberculosis, yet the combination pointed strongly in that direction. The radiograph, taken only two months before the death of the patient, was not of any diagnostic value. As a matter of fact, it was rather misleading in this case. It might be argued that further positioning should have been adopted, as, for example, lateral views; but as the A.-P. seemed to be within the bounds of normality this was not thought necessary. In mass radiography an A.-P. picture as obtained here may be thought sufficient for diagnostic purposes, but, as has been shown, this is not so.

The obvious conclusion, therefore, is that radiography is not the final court of appeal—at least in the early stages of the disease.

Radiograph of case

Reviews

INTERSEXUALITY

Hermaphroditos: the Human Intersex. By A. P. Cawadias, M.D., F.R.C.P. (Pp. 78. 15s.) London: William Heinemann, 1943.

In this, expanded version of his Thomas Vicary lecture Dr. Cawadias combines classical learning with modern endocrinology and morphology. He discards the label of hermaphroditism as too involved in mythological associations, and prefers that of intersex, which he defines as a morbid exaggeration of a normal process. He reminds us that sex is antenatally determined by the genes, the gonads being important executives. But the gonads of each sex carry vestigial remains of the opposite one, and experimentally we can inhibit or exaggerate the characteristics of each. He proceeds to a useful classification of types of intersexuality, though naturally there are varying degrees of overlap between them. There are: (1) The *gonadal*, in which the normal balance of the male and female elements in the gonads is upset. A virilizing tumour of the ovary is an instance of this. (2) The *genital*, in which there is a variable amount of malformation of the external and internal generative organs, which are normally moulded from a plan common to both, under the organizing influence of the original sex-forming impulse in the genes. This type then is due to an embryological fault. (3) The *morphological*, in which the secondary sexual characters and general bodily conformation resemble that of the opposite sex. This may be powerfully affected through the endocrine system; thus cortical adrenal tumours may cause virilism in women, while male subjects of hyperthyroidism may have feminine traits. Recent work on the excretion of androgens and oestrogens by both sexes, but in different amounts, proves that there is a bisexual basis here, the balance of which may be upset. (4) The *psychological*, affecting temperament and emotion. It will be seen that this classification allows for various degrees of intersexuality, while, so far as the last factor is concerned, environment may have considerable influence. Parents who are disappointed by the birth of a girl when a boy was desired not infrequently do the child life-long damage by attempting to mould her into something as much like a boy as they can.

Dr. Cawadias in his account of androgynoidism and gynandroidism emphasizes the view that it is the mild intersexes that are the most interesting, while the very rare monstrous ones, the so-called pseudo-hermaphrodites and hermaphrodites of our fathers, are useful principally for the understanding they afford the extremely frequent milder forms. Though space prevents his of his interesting discussion on "pragmatic sex" and "etic sex," the foregoing summary will make clear his use of these terms. When this lecture was originally delivered it gave rise to some controversy, as some thought that endocrine treatment of these disorders was regarded too optimistically. In the book before us not much objection can be taken on this score, even if some developments referred to belong to the future rather than the present. The rapidly increasing price of books is a disturbing phenomenon. This book of 78 pages costs 15s.

VIRUS DISEASES

Virus Diseases. By T. M. Rivers, M.D., W. M. Stanley, Ph.D., L. O. Kunkel, Ph.D., R. E. Shope, M.D., F. L. Horsfall, jun., M.D., and P. Rous, Sc.D. (Pp. 170. 52.00 or 12s.) New York: Cornell University Press; London: Oxford University Press, 1943.

Beyond the Microscope. By Kenneth M. Smith, F.R.S. Pelican Books (Pp. 112. 9d.) Harmondsworth: Penguin Books.

Two books have appeared recently which admirably present the achievements of virus workers to different classes of reader. For the initiated there is *Virus Diseases*, by six members of the staff of the Rockefeller Institute—not a textbook, but the publication in book form of six lectures given at Cornell University. Each of these is a fully documented monograph on a subject with which the author is closely identified, and represents an important advance, the scale and significance of which may surprise even the well-instructed reader. W. M. Stanley, who startled the world of microbiology some years ago by reducing the virus of tobacco mosaic disease to crystalline form, reviews further progress in the physical and

chemical study of plant viruses. Tobacco mosaic virus is now known to be a conjugated protein: it contains 15 amino-acids in accurately ascertained proportions, while four others are known to be absent. Chemical differences between different strains have been identified, and further study on these lines bids fair to demonstrate the chemical basis of mutation. The all-important question whether animal viruses, like plant viruses, must be considered non-living is discussed by Rivers and receives a qualified answer. His subject is the virus of vaccinia, the particles of which when photographed with the electron microscope have somewhat the appearance of dice—rectangular masses with darker spots on them. Kunkel's contribution on "New Hosts as a Key to Progress in Plant Virus Disease Research" tells a fascinating story of transmission experiments, in which aphides and other natural vectors are shown as far superior to the mechanical methods of the experimenter. Transmission to another host is often desirable because the natural plant host may be too unwieldy or slow of growth for experimental purposes, because it is desired to ascertain the resistance of the virus to heat by infecting a plant which itself resists very high temperatures, or—as in the case of one whole genus—because every plant of every species is infected and a normal natural host is therefore not available. Shope tells of swine influenza, discussing its possible origin in the human influenza pandemic of 1918, and describing how the virus is now known to have a cyclic existence, being conveyed annually from pig to earthworm and back by the swine lung-worm, of which the earthworm is the intermediate host. Horsfall contributes a statement of the present position in the study of human influenza, and Rous admirably summarizes the recent work, to which he himself has contributed so largely, on the part played by viruses in producing tumours. These are the high lights of modern virus work, and they are here presented in a form which makes good reading both for the expert and for the novice.

Beyond the Microscope, by Kenneth M. Smith, is a book on viruses in the Pelican series, and succeeds well in the difficult task of presenting highly technical material in a generally intelligible and attractive way without resort to the sensationalism which so often mars books of this kind. It might be expected that an authority on plant diseases would over-emphasize this aspect of the subject, but a nice balance is maintained between plant and animal pathology, and in treating some aspects of his subject the author deals with both types of virus together. This book shows that the subject can be made to have a wide popular appeal; apart from the romance of deadly if unfamiliar diseases such as yellow fever and hydrophobia it touches ordinary life at many points, both in the virus causation of common ailments and in such matters as colour change in wallflowers and the danger to tomato plants of smoking cigarettes in the greenhouse.

MEDICINE IN CHINA

China's Health Problems. By Szeming Sze, General Secretary, Chinese Medical Association; Editor, *Chinese Medical Journal*. (Pp. 60. 51.00) Washington: Chinese Medical Association, P.O. Box 6096.

The author of this, small volume was educated at a public school in England and at Cambridge University, and later had a distinguished career at St. Thomas's Hospital, whence he qualified. He then went out to China to dedicate himself to the Chinese medical profession. This book is the outcome of the information he has gathered on health problems and medical organization in that country. It can be said with truth that these problems are terrific and will take many years to settle. With the morbidity rate of 4% there are some 16,000,000 persons sick on any one day. In the whole country there are only 12,000 doctors and 38,000 hospital beds. On the basis of the usual medical standards China should have at least 266,000 doctors and 2,000,000 hospital beds. A large proportion of the population still rely exclusively on native medicine and native empiric methods of treatment. It will thus be seen that medicine in China is still in a very backward state; but, as the author shows, there is an active National Health Administration and Health League, both of which bodies are steadily working towards improvement. There are ten chapters, each dealing with a different health problem. The pros and cons are clearly and ably stated, and the work is a distinct contribution to this vastly important subject.

Notes on Books

Towards the end of 1934 the secretary of Grith Pioneers asked Dr. MARJORIE FRANKLIN whether a pioneer camp could be used to benefit youths whose behaviour problems unfitted them for normal society but who were suitable for environmental treatment and did not need specialized individual therapy. To answer this question practically, "Q Camp" was founded, and in 1936 the society opened Hawkspur Camp, near Great Bardfield, Essex. Annual reports have given some account of its activities; it had to be closed in 1940, but the society remains in being and is anxious to start again as soon as conditions allow. Meanwhile it has published the full story of *Q Camp*, its internal government, daily life, practical work, and a summary of what it accomplished. The community started in a field under canvas, and gradually housed itself in wooden buildings. Members came through physicians, the courts, social agencies, and other channels. They were a difficult party. Most of the selection was done at the Institute for the Scientific Treatment of Delinquency. Camp economics was an important instrument of treatment: it included wages, charges for board, lodging, clothing, and taxes, and a poor-rate to support non-workers. The staff regarded affection as the most potent factor for the readjustment of members, and used intelligently the phenomenon of transference. Punishment was limited to small fines imposed by the camp council. Three medical psychologists and an educational psychologist advised constantly on all aspects of behaviour. Government evolved by stages, including one of anarchy, into a genuine

democracy. In all 56 youths went through the camp. The authors candidly refused to be definite about results, or to attribute all the improvement in any case to the camp alone. They claim, however, that most of the members were helped to become happier and to have a better relation to society, to acquire a steadier and more genuine maturity and a sense of security, to lose much of their crippling guilt-sense, to turn their ill-regulated energies into useful and creative channels, and to improve their total personalities. Many ex-members have since done well in the Forces and in civil life. The report, price 1s. 6d., can be had from the secretary of the Howard League, Parliament Mansions, Victoria Street, S.W.1.

Social Therapy: An Introductory Study, by Lieut.-Cmdr. M. B. HALE, R.N., and S. M. HALE, a psychiatric social worker, is published by Williams and Norgate, price 5s. The authors are former members of the staff of the London Charity Organization Society, and they attempt to give an idea of social case work to anyone whose duty brings him into close personal contact with his fellow-men. It is firmly based on practical experience, and much of it has already been used as lectures to probation officers in training. It is more particularly intended to give material for discussion to first-year students at schools of social science and to workers in official and voluntary relief organizations. The authors discuss the main aspects of social work—buildings and equipment, interviewing, background, visiting, treatment, conference work, and records—from the standpoint of field workers whose attitude is rooted in Catholic religion tempered by a real acceptance and comprehension of modern psychology, particularly that of C. G. Jung.

Preparations and Appliances

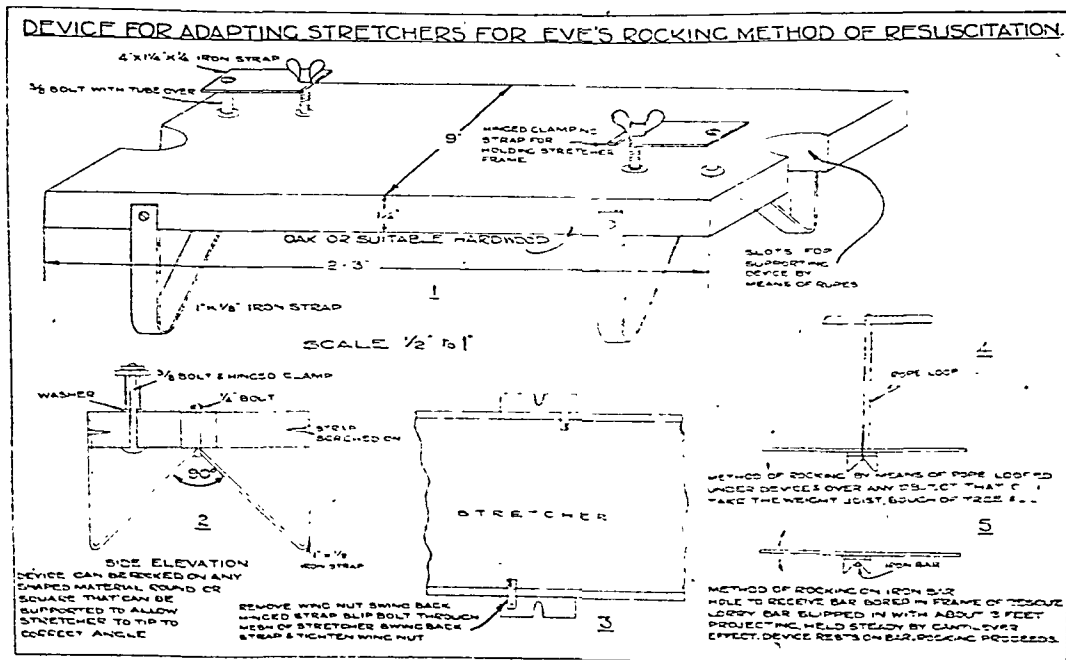

ROCKING DEVICE FOR STRETCHER

Dr. J. L. BARFORD, Medical Officer i/c Casualty Services, Surrey Control, Region XII, writes:

Increasing interest is shown in Dr. F. C. Eve's rocking method of resuscitation, but the various devices illustrated or suggested in your columns have not always been clear or easily adaptable to "incident" conditions and Civil Defence equipment.

device can be secured in a minute on to the stretcher which, already blanketed, is ready to receive the casualty.

The stretcher may be rocked either (1) suspended by a length of rope from a beam, etc., above; the loop of the rope fitting into the end slots in the wood block (Fig. 4); or (2) supported from beneath on almost anything, round or square—a trestle, crowbar, scaffold pole, 4 in. \times 4 in.-beam, etc., or an iron bar fitted in the undercarriage of the rescue lorry (Fig. 5).

Mr. R. Harris, Instructor at the Surrey County Council Rescue School, Leatherhead, has constructed a device (a print of which I enclose) for use with the Civil Defence stretcher, in almost any circumstances. It consists of a block of good hard wood (2 ft. 3 in. x 9 in.) slotted at each end (Fig. 1) and fitted on its under surface with two metal straps bent to 90 degrees in their centres (Fig. 2). The block is fitted on the under surface of the C.D. stretcher by means of hinged clamps (Fig. 3). The

In either case, the stretcher should be some 2½ ft. to 3 ft. from ground level.

I have seen the device in action and have 'satisfied myself as to its usefulness and extreme adaptability. It is easily made by a handyman, costs decidedly under 10s., and, apart perhaps from the block of hard wood, demands no controlled material. Surely all rescue service lorries might be equipped with this device and one made to form part of the equipment of every first-aid post.

SATURDAY NOVEMBER 6 1943

PENICILLIN IN THE U.S.A.

Penicillin is being manufactured on a large scale in the United States under a contract with the Office of Scientific Research and Development, and the study of its therapeutic use is in the hands of 22 groups of investigators appointed by the National Research Council. Their combined results in a total of 500 cases have now been published¹ in summary form, and papers on the treatment of individual conditions and giving more details are foreshadowed. This laconic and formidable report does not greatly amplify knowledge except in one particular; but by sheer weight of numbers it carries penicillin treatment to a more assured position than it possessed before, and to anyone who has not followed the progress of this work it must seem even more impressive. Of seven conditions chosen for treatment the first was staphylococcal septicaemia: 91 cases have been treated, in 54 of which there was complete recovery or striking improvement. That there should have been 34 deaths may seem disappointing, but some of these cases were inadequately treated either owing to shortage of supplies or because dosage had not then been defined, and some had complicating conditions such as extensive burns, endocarditis, uraemia, and cancer. Among 137 cases of staphylococcal infection without bacteraemia were 55 cases of osteomyelitis, the others having empyema, burns, and various infections of skin and subcutaneous tissues. Of these 109 recovered or improved, but this series cannot be fully appraised in the absence of information about the form of treatment and dosage. It

easy but extravagant to cure a localized infection by systemic treatment, and difficult but praiseworthy for its economy to do so by local application: how many of these cases had local treatment only is not stated. The results in 33 sulphonamide-resistant streptococcal infections, mostly due to *Str. pyogenes* and varying greatly in nature, were generally favourable: this series is small, and again details of treatment are necessarily lacking. There were 76 cases of pneumococcal infection, and perhaps the most encouraging feature among these is the response of sulphonamide-resistant pneumonia to moderate doses—less than 100,000 units given over a period of only 2 or 3 days. There were only 7 recoveries among 21 cases of pneumococcal meningitis, but some of these appear to have been treated before it was understood that penicillin does not enter the cerebrospinal fluid from the blood stream, and that intrathecal injection of penicillin solutions is safe and effective.

There remain two conditions in which the treatment was respectively a dismal failure and a success more complete than in any of the infections hitherto mentioned. Only 17 cases of subacute bacterial endocarditis were treated: 4

patients have died, 10 were unaffected and therefore presumably will die, while of 3 who showed improvement 2 relapsed soon after treatment was stopped. It seems that endocarditis of whatever kind is an unfavourable field for penicillin treatment: 9 cases of staphylococcal septicaemia with endocarditis all died, and of 6 having pneumococcal endocarditis only 1 recovered. In contrast to these depressing findings are the results which have been achieved in gonorrhoea. It was made known in the observations published from Oxford two years ago that the gonococcus is very highly susceptible to penicillin *in vitro* and clinical trial has been deferred in this country only because other conditions than gonorrhoea have an immeasurably greater claim on the scanty supplies available. We now have the answer to this question in quite unequivocal terms. Only sulphonamide-resistant cases were treated, to the number of 129: with the exception of 4, which apparently relapsed later, these cases were all cured by a few intramuscular injections of penicillin. Whether about 10 moderate doses or only 3 large ones are preferable has not yet been decided, but in any case the treatment takes not more than 48 hours and not more than 160,000 units of penicillin: even less time and material may serve the purpose.

A practically certain, very simple, and exceedingly rapid cure for the most difficult case of gonorrhoea seems almost too good to be true, but one could wish that it had been found in the shape of almost anything but penicillin. A demand from this quarter competing with the claims of antiseptics in battle wounds must present a dilemma of peculiar difficulty. There is so little immediate prospect of securing adequate supplies of penicillin that every addition to its uses must create further disappointment and increase perplexity in its allocation.

HOSPITAL PARTNERSHIP FOR SCOTLAND

North of the Border the question of hospital provision brings in rather different considerations from those which rule in England and Wales. For one thing, Scotland has a different tradition of local government; independent powers have been more freely entrusted to small municipalities. Scotland has also a peculiar distribution of population. Thus a division into five hospital regions, pivoting on the four medical schools and Inverness, is more or less accepted; but one of those regions, the south-west, contains more than half the total population of Scotland, and includes the most densely crowded Scottish city as well as almost the emptiest of its Highland spaces. Perhaps native circumspection has also to be considered. At all events the collaboration of voluntary and local authority hospitals in Scotland is nothing like that obtaining in some areas of England, and both sides approach the matter with caution. On the other hand, the Scottish characteristic of thrift has not manifested itself to any great extent in the form of the contributory schemes movement, and, again, Scottish voluntary hospitals do not generally attempt to recover treatment costs from their patients.

Last year a committee under the chairmanship of Sir Hector Hetherington was set up by the Secretary of State

for Scotland to consider the post-war development of a comprehensive hospital service on a regional basis. The main task of the committee, which has now reported,¹ has been to work out a method of partnership between voluntary and statutory hospitals. It is assumed that the dual system will continue after the war, but closer co-ordination will be needed if the comprehensive hospital service available to all, which the Minister of Health announced two years ago as the Government policy,² is to come about. To fuse into a coherent whole a local authority system, with its elected representatives and its public finance, and a voluntary system, with privately governed units, is no simple task, but it is assisted by the likelihood, as the committee judges it, that voluntary hospitals after the war will not be able to continue to offer the volume and range of their former service on the financial resources then available to them. They will need public grants, and a condition attaching to such grants will be that they must consult any regional body which is set up and adapt their programmes to a regional policy.

Many meanings attach to the word "voluntary." This committee defines a voluntary hospital as one which is not governed by any agency of central or local government, though it immediately goes on to describe as an encroachment on the voluntary principle the tendency of industrial contributors to seek representation on hospital boards—a form of consumer representation—which on this definition still does not make the hospitals any less "voluntary." One difference between the two types of hospitals is that voluntary hospitals do not as a rule pay their senior medical staffs, though, again, this tradition of honorary service is thought by the committee unlikely to persist: it would be an impediment to any partnership to have one set of hospitals continuing to work with an unpaid and the other with a paid medical staff. On the other hand, the committee thinks that the organization of local authority hospitals is in need of review. They should assign full clinical responsibility to the heads of their several clinical units, and the senior medical staffs should have independent corporate access to the governing body. In other words, let the voluntary hospitals treat their staffs financially in the same way as local authority hospitals, and let the latter accord to their staffs the status now enjoyed by the staffs of voluntary hospitals.

In addition to providing for interhospital co-operation, the Hetherington Committee has had to think out means for the collaboration of local authorities, for in the west of Scotland at all events no local authority, except Glasgow, is sufficient unto itself. The answer is found in the establishment of regional councils, which the committee thinks should be advisory bodies, though the Scottish Committee of the British Medical Association and the Scottish Branch of the British Hospitals Association hold that they should have executive powers. But the part taken by regional councils in hospital administration must not be regarded as unimportant nor reference to them as a matter of perfunctory routine. The committee suggests councils having equal numbers of representatives of local authority

and of voluntary hospitals, with an independent chairman and a salting of medical and medical-educational interests. The councils will first study reports on the needs and resources of their regions and the schemes propounded by the local health authorities, and will formulate a plan on which the Secretary of State will give his decision. Other functions of the regional councils will be to set up admission bureaux, under medical direction, to distribute patients among the various hospitals, to keep statistical records and to influence the filling of the more permanent medical appointments. It is suggested that the final appointments should remain with the governing body of the hospital but the governing body would receive a short list of candidates from a regional appointments committee, which would have enough prestige to make its recommendations acceptable. Altogether, the regional councils are to have such power that it is difficult to see how they can be purely advisory.

To finance the hospitals the committee proposes a compulsory contributory system. A payment of threepence a week is suggested, but this would meet only a fraction of the requirement and would need to be supplemented by Government subsidy. In this way it is reckoned that 60% of the total cost could be met. A central hospitals fund would be established and allocations made by the Department of Health both to local authority and to voluntary hospitals. The local authority hospitals would obtain the rest of their money from rates and Exchequer grants. The voluntary hospitals should be able to make up the difference as to three-fifths from their "voluntary" income and endowments, and as to two-fifths from public funds.³ The committee is anxious to preserve what may be called the "stimulus value" of the voluntary income which has supported up to now a couple of hundred voluntary hospitals in Scotland. But unconditional gifts and legacies cannot be expected to continue if their only object is to ease the local rates; they must be made to serve a distinctive purpose in hospital economy. It is suggested, therefore, that upon this voluntary income should be thrust the responsibility of providing funds for development. The shaft of the knife will be the allocated income from public funds, but the cutting edge will be the charitable contributions. It is felt that it should be left to the voluntary hospital to dispose at its own discretion of a substantial proportion of its voluntary income upon new enterprises. One passage in the report is very illuminating. In arguing that the voluntary principle, as expressed in the contributions of the charitable and the public-spirited, should be conserved for objects in line with the traditions of voluntary hospitals, the committee says:

"One of the main virtues of the voluntary system, and one which it is in the public interest to preserve, is the comparative freedom with which it can try out new techniques, new equipment, and new methods of

³ Estimated annual post-war expenditure of 219 voluntary hospitals in Scotland		
Payment from central hospitals fund (60%)	£1,500,000	£3,000,000
Interest on endowments (part)	£500,000	
		£2,160,000
Grants from local authorities and maintenance payments		£340,000
Voluntary income, free legacies, and endowments interest (part) (at hospitals' discretion for new development)		£504,000

¹ Report of the Committee on Post-war Hospital Problems in Scotland. Cmd. 6472, 1943. Edinburgh: H.M.S.O. (9d.)

² House of Commons, Oct. 9, 1941.

treatment which are promising but which have not reached a stage at which a public authority can or ought to be readily induced to incur the expense of introducing."

One hardly expected to find in a report which seems rather inclined towards the public authority point of view such a testimonial to private enterprise and such an implied criticism of the unadventurousness of official medicine.

MATERNAL AND CHILD HEALTH

Prof. James Young has surveyed the wide field of maternal and child health in the Honyman Gillespie Lecture he delivered at the Edinburgh Royal Infirmary last July.¹ Among other matters he emphasized the need for a much closer liaison between university medical schools and the public health services. Edinburgh has led the way in this respect, for a Chair of Child Health and Life was established in 1931 with Prof. Charles McNeil as its incumbent. Durham has recently followed suit. But London with its teeming millions and many medical schools has lagged behind. Were not traffic lights, trolley buses, etc., introduced in smaller cities some years before they appeared in the Metropolis? It is this cloak of conservatism hanging over the premier city of the Empire that irritates and at times exasperates the visitor. The idea of the combined school of maternal and child health is one which should be supported widely. The maternity hospital is preferably associated with the general hospital with all its ancillary services. This unit should be the common meeting-ground for teachers of obstetrics and child health. The proper study of the child is the child and the woman who bears and rears that child. The welfare of the mother during pregnancy is of paramount importance. After birth the health of the mother during lactation and later will profoundly influence the well-being of the child. Thus maternal and child health are indivisible and the professors of both subjects need to collaborate over a large common field, including nutrition, mothercraft, and the various social services that relate to family life and stability.

The paediatrician should be welcomed in the obstetric unit—in fact, invited to supervise and be responsible for all the infants. Yet there are still maternity units where he is looked upon as an intruder. It is more usually the senior sisters, inflexible and obscurantist, who are to blame in this respect. So often the paediatrician is called in when the infant is moribund. If there is to be any diminution in the annual wastage of infant life in this country (about 18,000 neonatal deaths and 25,000 stillbirths) then the paediatrician must have full control over the infant, normal and abnormal, from the hour of its birth. He must formulate the procedure for the feeding of the infants, for the care of the premature and the treatment of the infected babies. It must no longer be left to sisters and junior residents to make weighty decisions of this kind. We cannot hope for any improvement without combined operations on the obstetric and paediatric fronts.

Many will agree with Prof. James Young in his plea for the representative of the local authority, the medical officer

of health, being included on the academic council. In this way all the health services in a given region could be unified with benefit to all groups. A mass of clinical material which is not now utilized for teaching and research would thus be made available. By this arrangement the professors of obstetrics and child health would be made responsible under the medical officer of health for the clinical care and control of the mother and children of the area. A new era in the history of the medical schools would emerge, since all those wide social activities of the health authority that are related to the mother and child, such as mothercraft, nutrition, health education, etc., would be linked up with the teaching centre. For too long has there been a divergence between the workers in the municipal clinics and those in the hospitals. All too often does one hear of lack of cohesion. The artificially fed baby leaves hospital on a particular feeding regime and then is put on an entirely different one at the welfare clinic. The hospital has one system for ante-natal supervision, the municipal clinic another. The mother leaves the hospital where she has been confined and is examined post-natally by one who has no knowledge of her previous obstetric history. All this could be avoided if there were a common directorate and more team-work. There should be an exchange of duties so that, as Prof. McNeil has aptly said, the deadening effect of the treadmill of clinics could be avoided.

Under a partnership between university and local authority what a vista opens out, and what could be achieved for the benefit not only of mothers and children but of all members of the community! Prof. Young's plan is not premature, but it will need assistance in its delivery, which should not be too difficult unless obstructed.

"BRITISH JOURNAL OF INDUSTRIAL MEDICINE"

In January of next year we hope to add to the specialist journals published by the B.M.A. one which many felt should have been among the list of medical periodicals long before this—a journal of industrial medicine. Many informal talks on the need for such a journal have taken place during the past few years, and the final stimulus to action came in the shape of a formal request to the B.M.A. from the Association of Industrial Medical Officers, a body which has worked valiantly to promote the interests of industrial medicine. An editorial board was formed, and the names of five or six men put forward who would be willing to act as editors, under Sir Henry Bashford as editor-in-chief. For nearly a year Sir Henry has in fact been hard at work in preparing the ground, and more recently in assembling material for publication in the first issue, to appear in January, 1944. In view, however, of his new appointment as Medical Adviser to the Treasury he finds himself unable to continue the task of editor-in-chief, and it is anticipated that Dr. Donald Hunter will step into his shoes. Sir Henry will remain associated with Dr. Hunter in the editorial work, together with Dr. A. J. Amor, Dr. M. W. Goldblatt, Dr. D. C. Norris, Dr. Donald Stewart, and Mr. R. W. Watson-Jones. A distinguished and representative editorial board will support the editor with advice and encouragement and assist them in the formulation of policy.

¹ *Edinb. med. J.*, 1943, 50, 474.

One of the benefits of war to medicine is that it uncovers effects, whether in administration or in knowledge, and stimulates the medical profession to make these good. Apart from the devoted work of the medical inspectors of the Factory Department of the Home Office, the doctor has been a stranger in the world of industry in this large industrial country, possibly because the medical profession itself has been too preoccupied with the treatment of disease in the individual to the neglect of the wider questions of preventive medicine, both in the community generally and in industry in particular. With some notable exceptions, industrialists have been unimaginative in the matter, and only lately have realized the money value to industry of good health in the worker. Since 1939 the country has been overwhelmingly conscious of the extent to which it owes its safety to the health of the worker in industry; and in preserving this medicine must needs be of first account. Industrial medicine is not just industrial toxicology; in fact, industrial toxicology is but a small part of its subject-matter. There is a whole range of problems facing the worker, the management, and the doctor: the effect upon the worker and his work of temperature and humidity, of the intensity and direction of illumination, of posture and change of posture, of rest pauses and recreation, of washing facilities, of canteens, of an efficient accident service—not to mention the important psychological problems of monotony, relationship between foreman and worker, selection for work, and so on.

The value of the doctor in industry is now past dispute, and the future will probably see a rapidly growing body of knowledge coming from industrial medical officers, for they have an unrivalled opportunity for watching the effects of environment upon health, and also of teaching the people of this country the elements of hygiene—and if there was ever doubt about the need for this, experience during the war has dispelled it. From industrial medicine we shall hope to see a steady flow of original observation and research that will enlarge the frontiers of medical knowledge. Much of this work will, we hope, find its way into the columns of the *British Journal of Industrial Medicine*.

COCCIDIOIDOMYCOSIS

Coccidioidal granuloma (coccidioidomycosis), discovered by Rixford and Gilchrist in California in 1894, following a similar discovery by Wernicke and Posadas in Argentina in 1892, is a chronic granuloma-forming disease, sometimes presenting massive hypertrophic lesions of the skin or large subcutaneous cold abscesses. The lungs are very frequently involved; the spleen, liver, and osseous system, less frequently; and the genito-urinary and central nervous systems, occasionally. In its clinical features and morbid histology the disease resembles tuberculosis, the place of the tubercle bacillus in the lesion being taken by the large coccidium-like parasitic sporangium of the causal fungus, *Coccidioides immitis* (Stiles, 1897). For nearly half a century the disease was recognized only in the coccidioidal granuloma form, which is almost invariably fatal. It has an endemic distribution in small areas in the south-western States of America, about 89% of the cases occurring in California, where since 1928 the disease has been notifiable. About 46 new cases of coccidioidal granuloma are reported in the State annually, and the San Joaquin Valley is one of the worst endemic centres. There is little precise knowledge of its epidemiology, but the disease is not ordinarily transmitted from man to man, and infected migrants from endemic centres do not cause new foci of infection. Rare sporadic infections of cattle, sheep, and a dog have

been recorded, but are regarded as accidental. The frequency of pulmonary involvement points to infection by inhalation, and the relatively high incidence of the disease among agricultural workers and the remarkable skin lesions may suggest infection through the skin. Both these views are consistent with the discovery of the fungus in the dusty soil of a Californian ranch by Stewart and Meyer¹ in 1932. The recent notable advance in knowledge of the disease dates from 1937, when Dickson² identified in the "valley fever" of the San Joaquin Valley a relatively mild and hitherto unrecognized early stage of the coccidioidal disease. The symptoms are chiefly referable to the respiratory system, with fever, sweating, malaise, debility, and in some cases an exanthem like erythema nodosum. The incubation period, as shown by a group of people who contracted the infection during two days' exposure in an endemic area, is between 9 and 14 days. This early stage, in which recovery may be spontaneous, responds well to chemotherapy. The name "coccidioidomycosis" has been adopted, as coccidioidal granuloma is only a late and usually incurable stage of the disease.

The use of the "coccidioidin" dermal hypersensitivity test has carried the epidemiological study a stage further and shown that between 70 and 80% of apparently healthy persons who had lived for ten years in the San Joaquin area were specifically sensitive. The diagnostic value of the test is not proved, and confirmatory clinical, mycological, or radiographic evidence is desirable. Using this test, Aronson and his associates³ in 1942 got positive reactions in 90% of 141 Red Indian school children in the San Carlos Indian Reservation, Arizona, where coccidioidal granuloma was not known to occur. Following this discovery, Emmons and Ashburn⁴ in 1942 examined the desert soil in the San Carlos area and isolated *C. immitis* from 5 out of 150 samples taken from three widely separated sites. However, the high pathogenicity of the fungus for man and its rather meagre distribution in the soil pointed to something more than a wholly saprophytic existence in the desert, and attention was directed to the possibility of a reservoir of the infection in the small burrowing desert rodents common in the area, some of which were known to be susceptible to experimental infection. Among these the naturally acquired coccidioidal disease was identified microscopically and by culture in two species of "pocket mice" and one species of "kangaroo rat." These rodents seem to form a reservoir of the disease from which the soil is continually contaminated. In the wet season the fungus vegetates saprophytically in the soil, and in the dry season the wind-blown spore-laden dust carries the infection to man.

The new light on the epidemiology of the disease and the discovery of an early and curable stage have greatly improved the prospect of the eradication of coccidioidal granuloma.

Many members who are in touch with Headquarters will have heard already that Dr. G. C. Anderson had a severe and very painful heart attack on Oct. 23 and was taken from B.M.A. House to hospital, where he must remain for some time to come in absolute quiet. Dr. Anderson deeply appreciates the many messages of friendship and sympathy that are reaching him, but he may see no visitors at present and is forbidden to attend to any business until he is well enough to return to duty.

Reports of Societies

THE DOCTOR IN THE STATE: ANCIENT AND MODERN

The presidential address in the Section of Epidemiology and State Medicine of the Royal Society of Medicine was delivered on Oct. 22 by Sir WELDON DALRYMPLE-CHAMPNEYS, who gave a historical survey of the place of the doctor in the State from ancient times to the present day. Among those present were the Minister of Health (Mr. Ernest Brown), the Presidents of the Royal Colleges of Physicians and of Surgeons (Lord Moran and Sir Alfred Webb-Johnson), the President of the Royal Society of Medicine (Sir Henry Tidy), and the President and the Chairman of Council of the British Medical Association (Lord Dawson of Penn and Dr. H. Guy Dain).

Sir Weldon Dalrymple-Champneys began his survey with the "primitive" "medicine man." Most of them, he said, were inclined to despise this father of the craft, but Sir James Frazer, author of *The Golden Bough*, considered that, taking it all in all, he had done more good than ill to medicine and surgery. It was in this most primitive form of organized society that the doctor occupied the highest position in the whole of history, and yet never was choice of doctor less free! In the early stages of Chinese civilization the profession was at first represented by priests and sorcerers, but the medical student must ever bear China a grudge for having invented (tenth century B.C.) medical examinations. Babylonian medicine was mainly demonistic, but it had a remarkable scale of rewards and punishments, as witness the code of Hammurabi. The ancient Persians also had a scale of charges and bribes for doctors, and medical students were urged to "get their hand in" by practising surgery on unbelievers. In India the status of the physician was refreshingly elevated, especially during the Brahmanic period. In Egypt one of the remarkable features of its early civilization was the manner in which the details of public and private hygiene were regulated by ordinance. Moses not only adopted the numerous Egyptian dietetic rules but carried out careful researches of his own which he embodied in his code, to the great benefit of the Israelite people.

Sir Weldon then came to the fascinating spectacle of medicine in Greek civilization. Homer told how doctors were held in high esteem in the earliest days of Greece. The original Greek doctors were the priests of Aesculapius. In the fifth century B.C. arose the superb genius of Hippocrates, the first to trace disease to recognizable and intelligible causes. After referring to the famous school of Alexandria with its unique library, he referred to the medicine of ancient Rome, which provided a much poorer soil than Greece for the cultivation of medical practice. At the beginning of the Augustan age doctors still occupied a lowly place, and Rome was a happy hunting ground of quacks, but by the time of Constantine court physicians had become established, and there were medical officers for each district of the city, as well as for special classes—the vestal virgins and the gladiators. Of Arabian medicine he said that one of its great services was the establishment of well-ventilated hospitals, the first of which was in Baghdad. It was in the Middle Ages that an important change affecting medicine was brought about by Christianity. Even Hippocratic rule enjoined the doctor not to treat the incurable case, but Christianity reversed that.

After touching on the sources of medical learning in mediaeval Spain and Italy, and giving some account of the school at Salerno and the guild of physicians and apothecaries established at Florence in the twelfth century, Sir Weldon sketched the story of English medicine from the foundation of Oxford and Cambridge. The Royal College of Physicians was founded in the tenth year of the reign of Henry VIII, but even in those relatively enlightened days the apothecary was still a variety of grocer, the surgeon a variety of barber, and the physician just ceasing to be an ecclesiastic.

And so to the General Practitioner

The general practitioner of the eighteenth and nineteenth centuries in England was a man of keen observation, great independence, and one intimately acquainted with the life of his patients. In modern times two great changes had profoundly affected the life and work of the general practitioner—namely, the inventions and discoveries in physics and chemistry which had a bearing on practice, and the awakening of the social conscience to the demands of public health, with, in consequence, the ever-increasing concern of the State for the preventive aspects of medicine. Probably the most radical of these changes from the general practitioner's standpoint was that effected by the introduction of national health insurance in 1911. What was surprising was that a system which aroused such antagonism at its beginning should have now established itself so firmly in the affections of the profession in the course of 32 years

that a large section regarded the extension of its provisions to practically the whole population as the best way of bringing about a comprehensive medical service. It was generally agreed that the separation of much of the work done at clinics from the general supervision of the family doctor was unfortunate. The ideal arrangement would be continuous medical supervision of the individual from conception to death by the same person, and the preservation of the family unit as the basis of the general practitioner's work.

In conclusion Sir Weldon Dalrymple-Champneys pointed out certain lessons which were to be learned or certain warnings to be heeded from the survey of history. One of these was that decadence in medicine had coincided with the rising of specialties based on insufficient knowledge. Was it certain that this might not recur? Even in these enlightened days they knew of manufacturers launching new remedies on the markets, backed by extravagant claims not justified by scientific investigation, and doctors snatching at them in the hope that they might benefit a patient whom nothing else seemed to cure or even alleviate. The only sure defence against overspecialization was to give the general practitioner a dominant share in the care of the patient, but to fit him for that position he must be rightly educated.

The prevention of disease had a compelling appeal if presented by teachers who had the right outlook on health and disease. He refused to believe that the medical student of to-day—the brother of the radioclonologist—was incapable of feeling the fascination and satisfaction of detecting the first glimmering of ill-health in a patient and of adjusting the patient to the environment with the same pride and accuracy as the skilled member of the R.A.F. maintenance crew adjusted his instruments. No one expected the general practitioner to be an expert in environmental hygiene or in epidemiology, though he should be familiar to some extent with those subjects. But if he was to do his duty as the guardian of the patient's health he must know three things: his patient's heredity and environment; his medical history and present condition; and all the agents, including not merely methods of treatment but also the public and private organizations, which could be invoked to restore him to a normal or at least to a better condition. "I am convinced that the medical practitioner to-day is presented with a wonderful opportunity, which if neglected may never recur, of occupying a key position in medicine and in the State, and from that position, of exercising an incalculable influence for good on the health and happiness of his fellow-countrymen and winning for himself an abiding interest and satisfaction in the greatest of all professions."

Correspondence

Stomach and Mind

SIR.—The facts of the incidence of peptic ulcer and dyspepsia in the Army so ably presented by Sir Henry Tidy (Oct. 16, p. 473) are of the highest interest to clinicians and epidemiologists. They indicate most effectively how these disorders can be comprehended, treated, and prevented only if a psychological approach is employed to supplement a physical approach. The real conclusion of the paper—namely, the need for psychosomatic medicine—is not, however, mentioned by Sir Henry, who fails to emphasize (surely not to recognize?) that an isolated somatic approach to these disorders neither fits the facts nor works in practice—indeed, is not scientific in that by itself it can never make sense but only a kind of nonsense. Thus we find Sir Henry recording his experience of treating dyspepsia in such sentences as: "It is most important that these men should not be sent to hospitals or to specialists—procedures which are apt to convert a transient into a chronic dyspeptic and finally into a useless soldier"; and, again, "The longer the period in hospital the shorter is the interval to the next recurrence." In the absence of any qualifying psychological interpretation these extracts sound very queer indeed—the first like a passage from a manual of Christian Science and the second like an authentic quotation from *Alice in Wonderland*.

Yet the facts provided by Sir Henry do make a lot of sense when, and only when, a psychosomatic viewpoint is introduced. No more than a mere indication of this can be given in a letter, but observations such as the following would allow the facts to fall into place and permit of an interpretation which is coherent and not incoherent.

In civilian practice (and indeed in one's own personal life) sudden changes in climate, personal surroundings, food, and

degree of bodily exertion are frequently associated with disturbances of the gastro-intestinal tract, which represent the adaptation of the organism in both its physiological and psychological aspects to a new total situation. Sir Henry's observation that the treatment of such disturbances in hospital or by medical specialist serves to fix the symptoms and induce invalidism suggests that in adaptive dyspepsia psychological factors are on the average of greater aetiological importance than physical factors.

The gastro-intestinal tract may be profoundly disturbed in its function (and this in its end-results may bring about organic change) in the course of deep-seated emotional experiences. This has been beautifully demonstrated by Wolf and Wolf (*J. Amer. med. Ass.*, Oct. 31, 1942) in their account of the changes in stomach function directly observed in a man who had a gastric fistula. When this individual was free from upsetting emotional states, the appearance and secretion of the gastric mucosa could be described as normal; when he was under the influence of fear and sadness, the gastric mucosa was pale, with inhibition of secretion and contraction; but when he was involved in moods of anxiety or resentment, there was accelerated acid secretion with hypermotility and engorgement of the mucosa resembling hypertrophic gastritis. If the latter moods were sustained the vigorous contraction of the stomach frequently induced small bleeding-points. It is obvious, therefore, that the appearance of the stomach as seen by the gastroscope may depend on the inner emotional state of the patient at the time of examination, and that the findings of gastroscopy may be anomalous in the absence of psychological understanding of the patient.

Psychosomatic research has shown that the aetiology of peptic ulcer cannot be understood if psychological investigation is omitted, and that treatment which ignores psychological factors is impotent to prevent recurrence. It has also been shown that persons developing peptic ulcer tend to have particular characteristics—notably that of being unduly susceptible to threats to their emotional security, as is instanced by the occurrence of ulcer at times of occupational, financial, and domestic embarrassments. (Such threats are intense in the Army considered as a social field.) As regards epidemiology, it is also known that many "psychosomatic disorders" have shown a remarkable increase since the last war. This was demonstrated in the morbidity statistics of the insured population of Scotland, when not only peptic ulcer but also neurosis, gastritis, pseudo-rheumatism, etc., showed a remarkable relative increase as a cause of chronic incapacity (Halliday, *British Medical Journal*, July 2, 1938). The upward trend of those affections may be attributed to the increase of the noxious factors of social environment during the period. There are reasons to believe that these factors affected males relatively more than females (see Mittelman *et al.* in *Psychosomatic Medicine*, Jan., 1942).

To conclude, Sir Henry's record of the incidence of dyspeptic disorders in the Army is a valuable contribution to psychosomatic and to social medicine in that it demonstrates in respect of these affections how a purely "somatic" approach is inadequate as a method of interpretation, and how, if uncomplemented by a psychological approach, this outlook *per se* proves ineffective as a guide to therapeutic and preventive measures.—I am, etc.,

Glasgow

JAMES L. HALLIDAY.

D. and V. and Mastoiditis

SIR.—Dr. P. W. Leathart (Oct. 23, p. 526) has allowed his enthusiasm to outstrip his logic. He says: "In all cases in which bacteriological examination of the faeces proves the absence of a specific organism the diagnosis is incorrect and that of mastoiditis should be substituted." There seems to me more of dogma than of science in this confident assertion. The implications are that (a) all pathogens are demonstrable by routine bacteriological technique, and (b) where none is detected then mastoiditis exhausts the possible causes of D. and V.

Now with regard to (a), what would Dr. Leathart think of a police officer who said: "Sir, though you assert that you have been burgled that is quite impossible, since all the thieves known to us are accounted for and we have caught nobody?"

A virus would not be discovered in a plate culture made from faeces. Secondly, despite negative bacteriology, "non-specific" gastro-enteritis is an infectious disease. Few with experience of infant welfare would deny that it can spread through a ward or nursery almost as quickly as the common cold, which, for all Dr. Leathart or I know to the contrary, may well be due to the same agent. I do not understand how a germ can hop from one baby's mastoid to another's.

As for (b), without doubt violent gastro-enteritis with ulceration and destruction of large areas of gut does occur in many "non-specific" cases. Is Dr. Leathart acquainted with the cause or causes of ulcerative colitis? And would he recommend mastoidectomy for the relief of arsenical poisoning? The not unreasonable supposition that the mastoiditis may be secondary to an infection of the nasopharynx or to the act of vomiting, whereby septic fluid is squirted into the middle ear, seems to have been ignored, and as for the "parasympathetic reflex," why does this fail to manifest in mastoiditis complicating measles, etc.? Certainly the statement that otitis media with or without inflammation of surrounding bone does occur in association with D. and V. is not impugned, nor do I comment on the desirability of operation in such cases; but I must point out that the precise role of this factor in the total symptom complex has not yet been accurately assessed.

There is much fog about, but let us keep our heads. Fanaticism no less than apathy can lead us on to the rocks.—I am, etc.,

Grove Hospital, Tooting.

J. B. ELLISON.

Contraception and Sterility

SIR.—If the case that contraception induces sterility is based on the theory that certain methods may prevent absorption of semen from the vagina, we should surely consider this to be equally an argument against the "long engagement," which is so often the alternative to marriage with contraception; and indeed against the practice of pre-marital celibacy at all.

The contention that seminal absorption is necessary for stimulating fertility in some women is interesting, although there seems nothing in the breeding habits of the animal world to support it. Its verification would clearly rest with the research worker and statistician. I do, however, feel that the evidence Mr. Green-Armytage adduces could hardly be accepted as final. Some recent animal experiments he describes have been "unchallenged"—but there is not likely to be a plethora of workers with similar facilities eager and able to check up such matters. Nor, necessarily, is the quotation of views—from mainly American sources—to be taken as final arbitration. A similar number of opposing views, with or without context, can naturally be cited.

If any physician were to tell his patients that, say, the ingestion of tinned food is responsible for increasing sterility, there might well be none ready to enter the lists of experimental challenge. This would not imply that the doctrine was correct or generally accepted, yet the view would spread rapidly among the lay public, and would doubtless be still prevalent in twenty years. Mr. Green-Armytage is teaching his medical students and patients that contraception impairs fertility, and an anxiety is being fostered which is spreading rapidly, and which it is nobody's business to prove or disprove.

If it appears essential that data on this matter are produced, I am told that the Family Planning Association might be willing to accept the onus. Among its contraceptive clinics there are some hundreds of thousands of case records from which part, at least, of the data could be deduced. Taking multiparous women who have given a history of "no previous methods of contraception used," the time from the date of marriage to the first childbirth could readily be found. Others who give a history of previous contraceptive methods could, as they attend the clinics, be asked how many months had elapsed since their disuse and the subsequent conception. A few hundred records could be collected quite shortly, although the investigation would entail work and expense. If Mr. Green-Armytage would like himself to choose the statistician, I am sure the Family Planning Association would be in every way agreeable.

I do not find it possible to agree about the valuelessness of small clinics for advising on involuntary sterility. Mr. Green-

Armytage enjoys the facilities of a fully equipped central hospital, but this cannot solve the problem of the provincial or country woman whose vicinity very frequently offers no facilities at all. The increasing demand for this service throughout the country will obviously be met, sooner or later, by the equipment of proper "sterility units" in all provincial hospitals. But at the moment such facilities are sadly lacking. In many localities arrangements for seminal examination are absent or little short of archaic, and when abnormalities are found the "andrologist" who takes an interest is simply non-existent. Such conditions will doubtless be remedied within a few years. Meanwhile the small clinic, though its scope may often have to be limited, is giving a very real service to barren women, and one which it seems entirely unfortunate to disparage.—I am, etc.,

London, N.W.1.

JOAN MALLESON.

Sterility and Artificial Insemination

SIR,—Now that your columns are so full of letters on sterility, subfertility, and their treatment, it would appear to be opportune to point out that all the necessary investigations can be done in the out-patient department without giving the woman an anaesthetic—a fact which does not seem to be appreciated by a number of doctors.

Patency of the Fallopian tubes can be ascertained either on the x-ray table after injecting lipiodol, or on the couch in the out-patient department by utero-tubal insufflation without any previous preparation. The days immediately before or after menstruation should be avoided. Likewise with the patient on the out-patient couch an endometrial biopsy can be taken or cervical secretion aspirated for examination for live spermatozoa. It is as well to have a room available where the woman can wait for a few minutes should she feel any temporary discomfort.

Regarding artificial insemination, much has been said from the woman's point of view, and Dr. Pearse Williams (Oct. 16, p. 496) has mentioned the husband's point of view when he finds his wife is sterile, but little has been said from the husband's point of view when he finds that he is incapable of giving his wife one of her greatest desires. I have on several occasions been approached by the husband to ask if an artificial insemination could be performed on his wife from a donor, because he cannot bear the fact that he is the cause of his wife's disappointment, and he argues that he would rather have a child who has a 50% chance of possessing something of his wife than adopt one that possesses nothing of either of them. Granted it is not every woman who would prefer artificial insemination to adoption, but in cases such as this, surely there can be no psychological trauma to the child, and he woman, being satisfied, would be more likely to be drawn to her husband for gratifying her desire than estranged from him.—I am, etc.,

London, W.1.

M. MOORE WHITE.

Cos and Hippocrates

SIR,—It is with some hesitation that I venture to disagree with the distinguished medical historian who wrote the note on Cos and Hippocrates (Oct. 16, p. 492), but certain facts must be brought into the light.

The existence of Hippocrates is proved not only by the Dialogues of Plato but also by many other testimonies. He was considered a very great physician and universally honoured. Even the writings of later authors are sufficient evidence: (1) because they had documents which we do not possess; (2) because tradition in ancient Greece was a reproduction passed from brain to brain with far greater accuracy than has been necessary since the introduction of printed communication. We can see this high accuracy in the transmission of the poems of Homer, which were passed from brain to brain throughout the centuries and written only much later.

I agree with your contributor that there is no testimony that Hippocrates wrote the works known as the Hippocratic Collection; but certainly some other physician, probably of the same name, has given us the splendid writings which, to the reader with a medical, not philological, spirit, are remarkable (with the exception of two or three articles representing the teachings of other schools) for their unity of doctrine and

method, which represent distinctly a development of those previous medical schools, particularly Croton and Agrigen.

I cannot agree that the medical man of those centuries was regarded as a craftsman, an assertion which does not correspond with the facts. The Greeks, and Hippocrates himself, always distinguished between the craftsman (for which I must say with some shame, they had no great respect) the artist, a word which, in Hellenic mouths, indicated something very great. The physician in particular was very highly honoured. Homer speaks of him as "worth many other men." Nearly two centuries before Hippocrates three great Greek cities disputed the honour of having the physician Democritus within their boundaries, and prominent physicians received the highest civic honours. To-day the modern Greeks honour physicians above others, and the title of "Excellency" is given in modern Greek not to Cabinet Ministers or Ambassadors but only to physicians, and not only to the Athens professors but also to the highly respected village practitioners.

As for the relation between Hippocrates and the temple of Asklepios, the following are the facts: These temples were centres of religious psychotherapy. The Greek physicians were keen and unbiased observers, respected the power of this form of psychotherapy, and in the same manner the priests of Asklepios—prominent and cultured citizens—knew the importance of organic medicine. The relations between these kinds of healer were harmonious. Physicians usually frequented places at which there were shrines of Asklepios, medical schools were established near these shrines for the simple reason that in the absence of large hospitals the abundant sources of clinical material were the shrines of the god of medicine, where patients streamed from all parts of Greece.

After the first known Greek medical schools of Croton, Agrigentum, and Cyrene, there arose others at Cos, Cnidus, and Rhodes. The school of Cos is probably the most celebrated. Its teachings are concentrated in Hippocrates, who gave the highest intellectual and moral standards to our profession, and whose doctrine and method are influencing practice even to-day. Let us hope that the Greek flag will fly once more over the island, which, notwithstanding the attempts of the Italians during the last 25 years, has not lost its Hellenic spirit, and that again a wind from Cos will vivify our great art.—I am, etc.,

London, W.1.

Intercellular Hormones

SIR,—The research of Loofbourow and his colleagues discussed in the leader in the *Journal* of Oct. 16 (p. 487) throws light on the way in which ultra-violet rays used for treatment produce their beneficial effect. It is recognized that the dose must be such as to produce damage of the living cells of the deep layer of the epidermis, resulting in desquamation.—I am, etc.,

St. John Clinic, S.W.1.

LEONARD HALL

Adolescent Spondylitis

SIR,—I was very interested in Dr. C. W. Buckley's excellent paper on spinal arthritis in young subjects (July 3, p. 30). Some of the issues raised are very thought-provoking and deserve further research and investigation into a subject bristling with so many difficulties, both as regards diagnosis and treatment.

The late Dr. Gilbert Scott¹ has done a tremendous amount of original research into what he preferred to call "spondylitis adolescens," and his conclusions after the investigation of patients merit the attention of all workers in this field. I rather surprised that Dr. Buckley entirely ignored it, for he could not possibly have been unaware of the research on spondylitis which was carried on at the Charterhouse Rheumatism Clinic under the auspices of the Nuffield Wide-field X-ray Research.

Real advances in the diagnosis of this crippling condition began with the discovery of the changes which take place in the sacro-iliac joints 5 to 7 years before the onset of spondylitis in the young athletic male. In this pre-spondylitis

¹ A Monograph on Adolescent or Ankylosing Spondylitis, 1942, London.
² Bulletin of Wide-field X-ray Radiation, Research Report, 1939-40.

age treatment by wide-field x-ray therapy offers the best chances of an early arrest and symptomatic improvement. Out of 432 patients with adolescent spondylitis treated with wide-field at the above clinic 57.1% were much improved and symptom-free, and 15% were improved.

The results obtained by wide-field x-ray therapy offer a far more favourable prognosis than with any other methods of treatment—e.g., rest in plaster case combined with masterly inactivity—and I think that Dr. Buckley's outlook on treatment is rather too pessimistic. I can fully confirm the results obtained by Dr. Scott with wide-field x-ray therapy, but during the last 3 years I have combined the above with local x-ray therapy plus analgesic injections into the painful areas, and with some shortening in the length of treatment and more rapid amelioration of symptoms.

Diet, rest, physiotherapy—all have a place in the treatment of spondylitis, but with the addition of x rays (local and wide-field) to our armamentarium we have acquired a very powerful weapon in our fight against a very crippling disease. I hope soon to publish a paper on spinal arthritis with special references to wide-field and local x-ray therapy.—I am, etc.,

Capetown.

ARNOLD RAFF.

The Returning Service M.O.

SIR,—With regard to the recent correspondence on specialist and refresher courses for Service M.O.s, I feel that Dr. E. M. Leyland's letter (Oct. 9, p. 466) has described most clearly the difficulties and ambitions of many hundreds of the younger members of the profession who are serving in the Forces. I am certain that many, quite apart from any desire to specialize, feel the urgent necessity for further hospital experience on demobilization, but are worried as to how they will be able to obtain this with house officers' remunerations as low as they are at present.

Some of your readers may have noticed a report (*Times*, Oct. 14) on the comprehensive scheme of post-war aid which has been adopted by the Law Society. I think that the Law Society is to be congratulated on its planning and vision in devising a scheme which has these three main objectives: (1) to provide at the end of hostilities lectures and courses for the legal re-education of solicitors and articled clerks who have been out of touch with the law while on service; (2) to find employment for qualified men as soon as possible after demobilization; and (3) in the meantime to give those serving men who have time available all possible help to keep themselves up to date or continue their studies. A questionnaire has been sent to all known serving solicitors to ascertain their post-war needs.

The suggestions of refresher courses for Service M.O.s is but a facet, though a very important one, of the whole question of professional demobilization, which, it seems, has been somewhat neglected in the discussions taking place on the future of the profession as a whole. If the B.M.A. has a committee dealing with demobilization problems it is very silent about its activities, and if it has no such committee, I feel that the sooner it is constituted the better. The objectives of the Law Society post-war aid scheme might well be adopted, with some modification, by any such committee. The questionnaire idea will appeal to many.—I am, etc.,

R. E. OLIVER.

Arsenical Encephalopathy

SIR,—It is regrettable that Capt. C. B. Ainscow in his letter (Oct. 9, p. 465) disagreed with so much of our article on arsenical encephalopathy (May 29, p. 661). It is difficult in a letter of reasonable length to correct him on all the points raised. However, we hope the following will help him to a clearer view of the treatment of venereal disease.

Arsenical therapy is undertaken in pregnant syphilitic women in order to treat the foetus; treatment of the woman herself is left till after parturition. We quote the first two authorities to hand—namely, Harrison, chap. 21, and Earl Moore, chap. 19—in support of our methods. Capt. Ainscow suggests that our case of arsenical encephalopathy which recovered might well have been an eclampsia or other toxæmia of pregnancy. We stated in our article that this diagnosis was considered, but

the trace of albuminuria and the very slightly raised blood pressure were against it. The consulting gynaecologist who saw the case had no doubt that there was no toxæmia of pregnancy, and we prefer his opinion.

Capt. Ainscow's objections to the treatment of the only male in our series were met by Dr. A. O. F. Ross in a letter in the issue of the *Journal* of June 19 (p. 771). This case had been treated by Dr. Ross as an out-patient, and was sent into our wards actually comatose. It was explained in that letter that in spite of the history of a penile ulcer in 1910 the case was regarded as one of primary syphilis mainly because of the rapid changes in the Wassermann reaction. Capt. Ainscow apparently did not see this letter, and therefore we would like him to read it, and to inform him that Dr. Ross is chief V.D. officer to this city and can be fairly regarded as a venereologist of repute. We cannot accept Capt. Ainscow's view that the cases we described were examples of Jarisch-Herxheimer reactions. We have always understood that these reactions occurred within a few hours or at most within a day or two after the first injection. The changes we described occurred about the tenth day, and there were no untoward symptoms till almost immediately before coma; indeed, in the case of the male nearly three weeks elapsed before disaster occurred.

In our article pathological appearances of the brain were described in the cases which came to necropsy. We could not supply similar evidence in the case which recovered, even to satisfy Capt. Ainscow's curiosity.

We would like to assure Capt. Ainscow of our gratitude to him for reading our article, but would like to suggest that he should read it again.—We are, etc.,

F. GLYN-HUGHES.
R. B. NELSON.
C. MCGIBBON.

Liverpool

Pelvic Flexibility

SIR,—I am interested in the case of manual dilatation of the pelvis (Oct. 16, p. 484) as it draws attention to the cardinal fact that the mother's pelvis expands at the three joints—sacro-iliac and symphysis (at the same time the foetal head packs up at the sutures). The pelvis is expanded in the act of squatting much as the chest is expanded in the act of breathing, there is a pull on all the joints, and the area enclosed is increased.

But much better than any manual dilatation are ante-natal exercises designed to stretch the pelvic joints, ligaments, and perineum in preparation for the act of birth itself. This will be easier in the natural position—squatting or kneeling—right up to the last moment, when the mother can lie down for the actual delivery. Daily squatting for defaecation during pregnancy is a great help in avoiding constipation; at the same time it makes for pelvic flexibility, not only as regards childbirth but it keeps the athlete in trim. No first-class dancer, footballer, or rowing man has a pelvis with stiff joints, or he is old before his time; and a woman with a stiff and unyielding pelvis cannot hope for an easy labour.—I am, etc.,

London, N.W.11.

KATHLEEN VAUGHAN.

H11 for Cancer

SIR,—I have read with interest the various letters and articles regarding H11, especially as I have given a long trial to this preparation. The laboratory reports make interesting reading, but are they really important at this stage? What does it matter whether H11 checks or does not check growths in various mice in various laboratories if it is successful in the treatment of our patients? Let us hear, therefore, more about clinical results, and leave the laboratories to themselves for the moment.

My own experience of H11 is summarized by stating that I have had many failures and a few striking results, and the latter cannot be explained by mere coincidence. Herewith short details of one:

The patient was a woman of 58. Both breasts had been removed five years previously for carcinoma. Recurrence took place in the liver, orbit, and spine, and a huge mass grew out from the body of the ilium. She became blind in one eye, paraplegia developed, and she was rapidly going downhill. X-ray treatment was refused and only H11 in its original form was given. General improvement

began to show after a month's treatment, and within six months the liver had shrunk to half its previous size, the blindness was passing off, the paralysis was no longer present, and the mass in the ilium had disappeared entirely. The patient, who had been bedridden for months, was able to get up and lead an ordinary quiet life, spending part of the summer in the country sketching. She died two years later from what appeared to be a cerebral tumour. No one could fail to be impressed by such a result, especially when taken in conjunction with others.

At the moment I can only consider H 11 to be an adjunct to other forms of treatment, surgical and radiological. It appears to be an agent which, when certain unknown factors are present, can retard or even stop altogether the growth of malignant tumours. It is relevant to call to mind the stages of the treatment of diabetes by pancreatic preparations, and menopausal conditions by ovarian extracts. Successful results were few, but sufficient to induce further and patient experiment until to-day we have insulin and stilboestrol. So with H 11. There is enough evidence of success, I think, to demand from the profession a complete investigation into the possibility of developing this substance into a reliable remedy. In conclusion I would say that a visit to the Hosa Laboratories will quickly resolve all doubts as to the earnestness and importance of the effort that is there being made to solve one of the world's most serious problems.—I am, etc.,

London, S.W.7.

J. W. BARNETT.

Management of Acute Pleural Empyema

SIR.—The answers to Mr. Harold Burrows's questions (Oct. 9, p. 463) are to be found in my original paper (Sept. 25, p. 383). Dealing with non-localized empyemata, I said: "In such circumstances repeated aspiration of infected pleural effusion may be necessary. . . . In certain cases the same conditions may call for a water-sealed intercostal drain." Both these methods are effective and I use them frequently. The treatment of localized empyema may be by either open or closed drainage. Both these methods are, of course, satisfactory in the hands of those who are trained in their use. I do, in fact, frequently employ closed drainage. The point that I hoped to make was that perfectly adequate treatment could be given with the simplest possible equipment. When empyemata are being treated in general hospitals or under war conditions, often by those who have no great experience, I feel that the importance of adequate drainage by simple means cannot be over-stressed. The more we become specialized the more do I feel that we should try to simplify surgery rather than complicate it.—I am, etc.,

Leeds.

P. R. ALLISON.

Desert Sores

—The article by Dr. J. M. Henderson (May 29, p. 657) on the relationship of sunlight to desert sores prompts me to put forward a possible aspect of this relationship which has exercised my mind for some time.

The effect of the ultra-violet rays of the sun in decreasing the polymorphs, increasing the lymphocytes, and causing a "shift to the left" in the polymorph nuclei, has been shown by several workers. Shaw (1936) demonstrated the latter in Egypt and Kennedy (1935) in Iraq. Pellicciotta (1939) found neutrophilopenia and lymphocytosis with a shift to the left among white residents in Africa. Stammers (1933) says: "It is an established fact that ultra-violet irradiation leads to lymphocytosis." Does it not seem probable, then, that a neutrophilopenia due to solar irradiation, further increased in many instances by the common custom among the troops of sun-bathing, may underlie the reduced resistance to infection of some trivial injury? It is interesting to note that Corkill (1939) in the Sudan recorded a relation between increased insolation and increased incidence of cerebrospinal meningitis. Although he postulated a vitamin deficiency as the connecting link, I feel that diminution in the polymorphs might have something to do with it.

As regards the treatment of desert sores, I should like to suggest the application of a wad of gauze soaked in sterile peptone broth as used in the bacteriology laboratory. Applied night and morning for a week or two it often works wonders in cleaning up dirty ulcers and promoting healing. Its efficacy

makes me wonder whether the so-called "ultra-virus" preparations may not owe their action not so much to the product of bacterial growth as to the peptone broth which forms their basis. In some cases, after initial improvement an ulcer will again become "indolent," in spite of continued use of the broth. This accords with the experience of Rapport (1942) who, from his experience of treating desert sores, found that it was not advisable to persevere for longer than two weeks with any particular treatment, as the sores tended to acquire a tolerance to it. How the broth acts I do not know; possibly peptone water, or meat extract, or even saline dressings would work equally well. I have not access to sufficient cases to determine the question.—I am, etc.,

The Public Health Laboratories, Cairo.

Dentistry as a Specialty of Medicine

SIR.—Reading in your advertisements of whole-time posts for school and assistant school dental surgeons to the councils of large counties for which about £10 a week is offered, I feel the time has come for a discussion of the following questions.

1. Is the importance of first-rate work in dentistry for children of school age as part of preventive medicine realized by the authorities or ourselves? Can such work be done by the inexperienced or the out-of-date dental surgeon? Or whom otherwise do authorities wish to attract by such salaries?
2. Is there any reason, apart from custom, to look upon dentistry as anything but a fully equal partner among the specialties into which modern medicine and surgery necessarily subdivide?
3. Is it not time that the calling of the dental practitioner is put on an equal level with that of any other branch of medicine in its curriculum, medical and social standing, and its remuneration?
4. Would it not be essential to include a dental practitioner in any experiment with group practice that may be under way?
5. Would it not be in the interests of a profession which is charged with the maintenance of health in all its aspects to end the seclusion of one branch which requires, if practised at its best, as much knowledge, skill, and disinterested work as any other?
5. Should not medicine as a profession help in removing such outlived drawbacks of and prejudices against dentistry as still exist?
7. Have not the last twenty years or so given growing proof of the importance for health of good teeth and gums and of the significance of bad teeth as indicators and causes of disease elsewhere?
8. Should not the existing professional organizations unite in consultation and action on such questions of scientific, educational, organizational, and health-political interest as constantly arise at present?

My reason for writing is this. We need more dental doctors and more of them who attain the highest standards. We cannot expect to get them unless we give this medical specialty the honour which is its due, and the partnership which, on theoretical and practical grounds, it deserves. Dental medicine and surgery are doing good work. Witness the collaboration of dental surgeons with plastic units or the outstanding book on *The Principles of Dental Medicine*, by F. W. Broderick. I myself am neither a dental surgeon nor related to one.—I am, etc.,

London, W.1.

L. MICHAELIS.

Hospital Posts under Local Authorities

SIR.—The letter from Mr. Edgar W. Thomas (Sept. 25, p. 405) on appointments to hospital posts strikes a sympathetic fibre in my being. For years have I, in and out of season, striven to bring before the profession the iniquitous system of selection perpetrated on unsuspecting aspirants for appointments to the staffs of provincial hospitals.

Mr. Thomas says: "This system whereby lay committees appoint medical men to hospital and other posts is both ridiculous and demoralizing." I would point out that the fault does not lie with the lay committee: they merely go through the form of making the appointment; their crime is one of ignorance. The real appointment is made by the medical committee of the hospital; they are the "bandits behind the

CORRESPONDENCE

Nov. 6, 1943

scenes," who have their own nominee incubating and all ready to burst forth from the egg of vested interest as assistant physician or surgeon. He is generally a junior partner or a man who has bought the practice of a member already on the local staff: he has "bought himself in."

For years I have pointed out the injustice of this system of staff appointments and how it has grown to be a racket which brings neither honour nor efficiency to our hospitals. I agree with Mr. Thomas that the system is both ridiculous and demoralizing and a few more things as well. "Local politics" do not enter into it, but "graft," yes; and it is the medical men who are to blame. In order to break this disreputable trade in medical appointments the matter should be taken out of the hands of local committees, lay as well as medical, and placed with the Ministry of Health or other impartial body.—I am, etc.,

Bournemouth.

VINCENT NORMAN.

The Classics in Medical Education

SIR.—I trust you can give me a little space to protest against Prof. Major Greenwood's conditional plea for making Latin a compulsory subject of medical pre-education (Sept. 18, p. 375). If there is any of that increasingly precious commodity time to spare, in Heaven's name let it be spent in preparing the student in a realistic way for the problems he is likely to meet. Surely a course on scientific method is likely to be much more valuable than acquiring the ability to construe the Latin authors, and, in fact, has been left far too long out of the curriculum.—I am, etc.,

London, W.1.

FREDERICK DILLON.

Unity in the Profession?

SIR.—My letter (Sept. 25, p. 405) makes it perfectly clear that it is to Dr. Buchan's views on State medicine (Aug. 28, p. 278) that I am opposed. I do not possess Mr. McCurich's knowledge (Oct. 17, p. 496) of his activities in the discussions with the Government. I am quite aware that he was chosen by the Society of Medical Officers of Health—a component of the Representative Committee. I carefully made no reference to his having been chosen by anyone. The B.M.A. did choose at least one member of that Society and others whose views in the past have closely corresponded with those of the M.O.H. group. I still maintain that men with such views should not be elected to the future negotiations committee. It seems ludicrous to have them when unity of outlook and purpose is essential on so vital a committee.

The drawing of his obviously false inference gave Mr. McCurich the opportunity to write a letter in which he lifts the edge of the veil which, I believe, perhaps in ignorance, is still tightly drawn over the discussions between the Representative Committee and the Government. I wonder who authorized this? Mr. McCurich complacently states that "they [M.O.H. group] presumably will let the G.P.s settle what they want." Will they? I glean from Dr. Buchan's letter that the M.O.H. group desires full State medicine and to control it, but there is no need for haste. I would be among the first to agree with Mr. McCurich concerning Dr. Buchan's knowledge of his job and of the administration of Government Departments. The overlappings and confusion in these various Departments should be straightened out, in spite of the fact that they are notoriously jealous of the scope of their administration.

It is not with the integration of the various Departments and the Public Health Services that I am particularly concerned. I would leave that to Dr. Buchan and others like him who know about it and who are capable of dealing with it. Such men should be on the Government side of the fence when negotiations begin. It is in the future position and status of the general practitioner consultant group that I am interested. Their representatives on any future committee should be "elected"; and to give doctors a proper opportunity of voting correctly candidates for election should issue a manifesto stating clearly their views. The present official position of any doctor or surgeon in any society should not make him *qua non* a member of this vital committee.

It is quite possible that by holding such elections some experienced men may be passed over, but a committee so

elected, with a clear policy and backed by the profession, will be able to negotiate with strength. So it seems to me now the discussions are over.—I am, etc.,

Bradford.

DONALD WATSON.

The Human Side of Medicine

SIR.—So generous was the review of my book *The Future of Medicine* (Oct. 23, p. 513) that I hesitate to disagree with it in any way, but there are two points I think I ought to make clear. Dr. Alfred Cox speaks of "the somewhat inhuman attitude of the convinced Socialist," and against this I must protest. If there is one thing which marks the Socialist case off from others it is the fact that it is more human and more humane than any other. Writing a very small book on such a large subject one necessarily has to compress, but I thought I had managed to make my writing reflect my own intense desire for an improvement in the general conditions of the great majority of individuals who comprise the community we call Great Britain. Dr. Cox can be assured that I have tried out the ideas expressed in *The Future of Medicine* on many audiences of ordinary common folks in Lancashire, Yorkshire, and many other parts of the country, and I have never met with anything but the most enthusiastic support.

A second minor point is that Dr. Cox puts into quotation marks the phrase "more likely to be treated as a human being than in a voluntary hospital," and says that I made the statement on page 42 about the patient in a public hospital. I cannot find these words on page 42, or on any other page of the book. The phrase, which he has evidently paraphrased, was a quotation from the well-known report of P.E.P., which actually stated that in the hospital of a local authority a patient "is treated less as a case and more as a human being."

These two points are not so far divorced as one might imagine: they are both concerned with the human side of medicine, and it is obvious that observers differ as to their interpretation of what is human treatment. I believe that the change over from an individualistic system of medicine to a comprehensive national service will give us the opportunity to humanize completely the relationship between patient and doctor, and at the same time to raise the efficiency of our medical services to a point where our existing knowledge can be fully applied.—I am, etc.,

Richmond, Surrey

D. STARK MURRAY.

Obituary

ERIC PRITCHARD, M.D., F.R.C.P.

Eric Pritchard, who died at Exmouth on Oct. 20 after a long illness, was widely known for his work, extending over thirty years, in the cause of infant welfare. He was a pioneer in many aspects of child hygiene, a brilliant organizer of infant care, and a lecturer and writer of distinction, but his crowning work was his fourteen years' medical directorship of the Infants' Hospital, Vincent Square, Westminster. This post, to which he was appointed in 1922, was rather an uncommon one in British hospitals. It was created to meet the need for a hospital dealing exclusively with children, which, like other hospitals of the kind, had suffered from the diversion of public attention during the years of the last war. When, owing to Pritchard's efforts and those of the generous friends whose sympathy he enlisted, an annexe was opened, bringing up the accommodation to 100 beds and the new out-patients to 3,000 a year, it claimed to be the largest hospital of its kind in the British Empire.

The Infants' Hospital remains in a sense Pritchard's monument. Those who went round the new extension under his guidance were impressed not more by the originality of the design and planning than by the enthusiasm of the medical director. The arrangements for ensuring light and ventilation and avoidance of cross-infection, the open-air balconies to which every ward and wardlet had access, the provision of a locker for each infant, with all toilet requisites and thermometer, the clinic for deaf and partially deaf children, everything from the special floor to the special ceiling betokened Pritchard's mind. Most of all he delighted in the lecture hall.

This was a very unusual apartment, presented by Sir Robert Mond as a psychological experiment in the influence which beautiful surroundings might have upon the words of a lecturer, and especially upon the responsiveness of his audience. It had exquisitely carved panelling, fretted roof, and delicately traced lattice windows, and Pritchard confessed that when he first saw it the attractions of its rostrum for teaching purposes contributed largely to his acceptance of the post of medical director. Here for fifteen years he gave postgraduate lectures in connexion with the Fellowship of Medicine and the London Public Medical Service—three courses a year, each course consisting of at least twelve lectures. Before this, from 1909 to 1922, he had given short courses at the Queen's Hospital for Children, Bethnal Green, to which he was consulting physician, and even earlier still, in 1906, he had begun similar courses of lectures at St. Marylebone General Dispensary, where he was first medical officer to the first infant welfare clinic in London to be started by voluntary effort. Altogether he claimed to have given at least 1,500 lectures on child care.

George Eric Campbell Pritchard was born at Freshwater, Isle of Wight, in September, 1864, the son of the Rev. Charles Pritchard, D.D., Savilian Professor of Astronomy at Oxford. From Clifton College he went on to Oxford, where he took his B.A., with first-class honours in physiology, in 1887. He went for his medical training to St. Mary's Hospital, London, where he held a university scholarship, and qualified in 1892. In 1899 he proceeded M.D., and in 1926 became Fellow of the Royal College of Physicians. He also spent some time in study at the University of Berlin. Quite early in his career he devoted his attention to paediatrics, and for three years he was medical inspector of schools for the L.C.C. In due course he became a consulting physician in Marylebone and held several hospital posts. For some years he was paediatrician to Queen Charlotte's Maternity Hospital. Another post he greatly valued was that of consulting physician to the Sunshine Homes for Blind Babies, a project of the National Institute for the Blind.

It is not easy to catalogue the work of a more public kind which Eric Pritchard carried out for the medical supervision of the child in sickness and the preventive programme of the child welfare services. The steady decline in infant mortality during the last thirty years cannot be ascribed to one cause, and certainly not to one man, but among the names of those, apostles, educators, organizers, who helped to bring it about, that of Pritchard would be conspicuous. The offices he held at one time or other, to all of which he gave fully of his energetic and conscientious personality, show the concentration of his interest. He was honorary secretary of the National Association for the Prevention of Infant Mortality and of Child Welfare, chairman of the Association of Infant Consultations and Schools for Mothers, and of the executive committee of the National Baby Week Council, president of the British Paediatric Association, and vice-president of the Child Study Society. He had been president also of the Section for the Study of Disease in Children of the Royal Society of Medicine; and in the British Medical Association, of which he had been a member for nearly twenty years, he was vice-president in 1923, and president ten years later.

Pritchard's literary output was considerable. His *Physiological Feeding of Infants and Children* passed through several editions, and he wrote other books. After his retirement he published *The Infant: a Handbook of Modern Treatment*, written for occasional reference by the general practitioner. "Infancy" he interpreted as meaning the first five years of life. He never hesitated to be unorthodox if he thought that the principles of child health demanded it. His instructions to nurses and to "nannies" may sometimes have been resented as "new-fangled notions," but those concerned came to admit that there was a great deal in "what Dr. Pritchard said." He was specially interested in the work of the Wellgarth Nursery Training College in seeing that those who had to deal with babies and young children received adequate training in nutrition and hygiene. He himself was not only learned in the principles of paediatrics, but he had a remarkable "way with children" which accounted in no small degree for his success.

A correspondent writes: Of Eric Pritchard the clubman, the bridge player, the *bon viveur*, some brief record should remain. To this side of life he brought an unflinching zest; if his bridge calls were on the side of undue optimism, he was never cast down by defeat, and his glee was manifest when he did pull off a slam bid, especially if it was accomplished through a lucky opening lead or a series of bold finesses. He had a schoolboy flair at inventing nicknames for his fellow clubmen, and these had a habit of sticking; they often embodied personal peculiarities; but the victims rarely felt annoyed, as they were obviously concocted in a spirit of good-natured fun. His judgment of vintage port was retained into old age. Occasionally hot-tempered, and apt to be both mordant and emphatic at such times, he could always be placated by a soft answer.

A. PIRIE WATSON, CH.M., F.R.C.S.ED.

We regret to announce the death, at his home in Douglas Crescent, Edinburgh, on Oct. 22, of Mr. A. Pirie Watson, for many years a leading surgeon and teacher of surgery in the city. He had been on the honorary staff of the Edinburgh Royal Infirmary since his election as assistant surgeon in 1911 and only two days before his death he was re-elected to the Council of the Royal College of Surgeons of Edinburgh, of which he became a Fellow in 1911.

Alexander Pirie Watson was born at Aberdeen in 1880 and was educated at Trinity Academy, Leith, and Edinburgh University, where he graduated M.A. in 1903, M.B., Ch.B. in 1905 and Ch.M. with gold medal in 1911, in which year he won the Syme Surgical Fellowship and the Chiene Medal in Surgery. From 1908 to 1914 he held junior posts at the Edinburgh Royal Infirmary, and for 14 years he was assistant to Prof. Alex. Thomson in the department of surgery at the university. Mr. Pirie Watson was closely associated with the Leith General Hospital during the past 24 years, where he was successful pathologist, assistant surgeon, and surgeon. He had held commission in the Territorial Army for years before the last war, and in 1915 went over-seas with the 52nd (Lowland) Division. He served with the 4th Royal Scots throughout the Gallipoli campaign; later he became A.D.M.S. of the Division and took part in Egypt in the defence of the Suez Canal and thereafter in the Palestine and Syria campaigns. He was present at the capture of Jerusalem and commanded a mobile unit, and for his services in the campaigns he was twice mentioned in dispatches and received the O.B.E. (Mil.). On returning to civil life he was promoted lieutenant-colonel in command of the 11th (2nd Scottish) General Hospital in 1925, and later colonel and A.D.M.S. of the 52nd Division, and received the Territorial Decoration.

Early in his career Mr. Pirie Watson made a close study of the treatment of fractures. He contributed articles on the treatment of injuries to Murphy's *Practical Encyclopaedia*, to fractures and dislocations to Sorapure's *Dictionary of Therapeutic Agents*, and on amputations to Miles and Wilkie's *Operative Surgery*, also a number of papers to the *Edinburgh Medical Journal*. He had been a member for many years of the British Medical Association, and of the Edinburgh Medical Chirurgical Society and the Edinburgh Pathological Club, and he was a Fellow of the Association of Surgeons of Great Britain and Ireland.

Dr. WILLIAM ROLLAND died at Bolton on Oct. 15 at the age of 59. By his death the town and the Royal Infirmary sustain the loss of a practitioner who had played a most important part in the medical life of the community. Owing to the fact that he had been an assistant to Prof. Muir of Glasgow he was able in 1911 (when appointed to the honorary staff of the Bolton Royal Infirmary) to start the pathological department, which has grown from its humble one-room beginning to the up-to-date laboratories which house its activities to-day. Rolland also initiated the medical side of the hospital and acted as honorary physician; there also he worked hard and showed himself to be a careful and conscientious clinician; but he was also a pathologist, and perhaps especially as a bacteriologist that he achieved an almost unique position. Lancashire has now and then produced, in its provincial towns, a doctor of distinction; everyone remembers Mackenzie of Burnley, and one ventures to think that Rolland of Bolton is equally entitled to remembrance for the great work he did in making the pathological service of the Royal Infirmary the foundation for all the clinical progress that has since been made there. During the last war he served from 1915 to 1918 as pathologist at No. 24 General Hospital, France. He leaves a wife and a son, Charles, who is a final-year medical student; his young son, Graham, was killed recently on active service in the R.A.F.—J. L. F.

Dr. WILLIAM STEVEN of Featherstone, nr. Wakefield, died on Oct. 15 at the age of 81. He was a native of Forfarshire and graduated M.B., Ch.M. at Edinburgh in 1886. Fifty-seven years ago he went to Featherstone as assistant in the practice of which he later became the head. No one was better known in the district or among his professional brethren than he. He was M.O.H. for the district and took a very keen interest in all public matters connected with his profession. For fifty years he was an instructor and examiner for the Order of St. John of Jerusalem, and at the time of his death was an Officer.

Dr. Mary M. Patterson writes: As a colleague of Dr. HANNAH PERRY ANDERSON, whose obituary notice appeared in the B.M.J. of Oct. 23, I would like to add a word of appreciation. Dr. Anderson was a remarkable woman in many ways. She did not enter the medical profession until she had reached an age when less active and alert women are contemplating a life of leisure and retirement. Already she had lived through a very full life, and had travelled all over Europe when she accompanied her husband, Professor Anderson, to his many and varied scientific gatherings, when she met most of the leading scientists of the beginning of the century. When Dr. Anderson became a widow she at once commenced her medical studies with the ardour and enthusiasm of youth. It was a new adventure to her, and to the last hour of her life it remained an adventure. She was eager and ready for any phase of her work and enthusiastic in the work and aspirations of the younger members of the profession. Her breadth of view, her wholesomeness, her joyous optimism, inspired patients and colleagues alike. Like many another, I mourn the loss of a brave, staunch, and trusty friend.

Neonatal Discharge.

2.15 p.m., at the College.

The following having satisfied the Censors:

Members of the College:

Enid I. M. Addenbrooke, M.B.; C. Beattie, M.D.; J. A. Black, M.B.;
Joyce E. Chamberlain, M.B.; P. J. Colhard, M.B.; A. H. C. Couch, M.B.;
L. M. Dunlop, M.D., F.R.C.P.E.; F. Foran, M.B.; O. F. Garai, L.R.C.P.;
D. Greenfield, M.B.; P. Harvey, M.B.; V. H. Helms, L.R.C.P.;

Pragnell, J. E. L. Price, V. W. Pugh, Denise A. Pullen, Celia M. Rapport, D. A. C. Reid, J. I. Rivlin, J. W. Robb, D. G. Roberts, M. M. Rose, D. Rosenberg, M. H. Russell, N. H. Seaton, D. L. Scott, M. Seifert, J. C. Seines, J. H. Sherry, L. S. Simons, K. H. Smith, W. H. Smith, J. L. Souster, Ethel M. Spedding, I. F. R. Sutherland, C. E. Sweetnam, K. B. Thomas, D. W. Townley, J. K. Trounce, K. A. D. Turk, H. R. Vincent, B. A. Ward, J. S. Watson, W. A. Watson, P. L. Watts, J. Wedgwood, G. P. West, R. G. White, T. A. White, K. C. Willett, H. B. L. Williams, O. H. E. Williams, T. C. P. Williams, A. M. Wood, C. F. Zervogel.

Diplomas in Child Health (eighteen) were granted, jointly with the Royal College of Surgeons of England, to the candidates whose names appear in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Oct. 30 (p. 562).

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the annual meeting of the College held on Oct. 20 the following office-bearers were elected for the ensuing year: *President*, Prof. R. W. Johnstone, M.D., F.R.C.O.G. *Vice-President*, Mr. J. W. Struthers. *Secretary and Treasurer*, Mr. K. Paterson Brown. *President's Council*, Mr. James M. Graham, Sir John Fraser, Bt., Mr. A. Pirie Watson, Dr. G. Ewart Martin, Mr. Francis E. Jardine, Mr. W. Quarry Wood. *Representative on the General Medical Council*, Mr. Henry Wade. *Convener of Museum Committee*, Mr. W. Quarry Wood. *Librarian*, Dr. Douglas Guthrie.

The following candidates, having passed the requisite examination, were elected Fellows:

W. Cowell, E. Griffiths, W. G. Holdsworth, A. M. Howard, S. L. Mann, A. G. C. Neill, St. J. G. O'Connell, C. C. Slack, H. B. Young.

The Services

Lieut.-Col. H. H. Elliott, C.I.E., M.C., I.M.S., has been appointed Surgeon on the personal staff of the new Viceroy of India, Lord Wavell.

Capt. (temp. Major) A. Cregar and Capt. L. Herbert, J. E. Miller, and E. L. Moore, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Sicily.

The Efficiency Decoration of the Territorial Army has been conferred upon Lieut.-Col. (temp. Col.) (local Brig.) A. H. Whyte, D.S.O.; Lieut.-Cols. (temp. Cols.) A. T. B. Dickson, O.B.E., and I. M. Pirrie, M.C.; Major (temp. Lieut.-Col.) (acting Col.) A. H. Macklin, O.B.E., M.C.; Majors (temp. Lieut.-Cols.) J. B. Forsyth, R. M. Gordon, A. B. Kerr, W. R. Logan, R. W. Power, and W. B. Sprunt; Majors W. C. Armstrong, R. E. Holme, W. H. M. Jones, W. L. Lamb, M. Stoddart-Scott, C. M. Willcox, and J. Wright, R.A.M.C.

The Commander-in-Chief of Bomber Command has commended the action of a medical officer, Flying Officer A. R. H. Mills, in swimming a river to the rescue of some stranded airmen. When a bomber crashed by the side of one of the main rivers of the Midlands F.O. Mills entered the water and swam across in the dark. He managed to release the dinghy, and first ferried the fit members of the crew across. He then procured stretchers and safely transferred three injured men to an ambulance.

CASUALTIES IN THE MEDICAL SERVICES

Lieut.-Col. Stewart Brown, R.A.M.C., was killed in action at the age of 31 in the Central Mediterranean area while tending wounded. He was educated at George Watson's College and the University of Edinburgh, where he graduated M.B., Ch.B. in 1935. At the Army Medical College, Millbank, he was medalist in

military medicine, then saw service on the North-West Frontier, later in Palestine and Egypt. He was promoted major and to the 51st (Highland) Division while being re-formed in this regiment went over-seas again with the Division, and served all through campaign in North Africa to Tunis. He was then promoted colonel and given command of the City of London Unit in the Middle East.

Wounded.—War Subs. Capt. J. H. F. Brotherton, R.A.M.C. *Previously reported missing, now officially reported a prisoner of war*.—Capt. G. F. Allan, R.A.M.C.

Prisoners of War.—Fl. Lieut. R. A. Cumming, R.A.F., Fl. Lieut. W. N. Riley, R.A.F.V.R.

Killed.—Capt. H. G. Greeves, R.A.M.C. *Killed on active service*.—War Subs. Capt. R. E. K. Lee, R.A.M.C.

Officially reported died on active service.—Capt. I. G. ... R.A.M.C.

Medical Notes in Parliament

Mass Radiography

Mr. JACKSON asked on Oct. 14 at what intervals Mr. Brown advisers considered it necessary to examine people by mass radiography to be satisfied that they showed no early traces of tuberculosis. Mr. BROWN said signs might pass from the radiologically imperceptible to the perceptible state in the interval between two examinations, however short the interval, and frequency of examination could give complete security. The practical question now and for some time to come must be how to make best use of the resources available. Miniature radiography units had been supplied in England to the Councils of London, Lancashire, Middlesex, and Surrey, and to the Staffordshire, Wolverhampton, and Dudley Joint Tuberculosis Board. Another unit had gone to Scotland. One was on the point of delivery to the Welsh National Memorial Association.

Repatriation of Disabled Prisoners

On Oct. 19 Mr. LAW made a statement on the repatriation of disabled prisoners of war. He said that two agreements had been reached with Germany which covered all those members of the armed Forces of the British Commonwealth and of the United States who had been passed by medical authorities for repatriation under the Geneva Convention. In all, there were over 3,000 seriously sick and wounded, the great majority of them members of the United Kingdom Forces, who were coming home from Sweden, as well as 1,200 or more officers and other ranks, including doctors, chaplains, medical orderlies, and stretcher-bearers. They would leave Gothenburg on Oct. 20 or 21. In addition, more than 1,000 men, members of the Dominion or Colonial Forces, would be brought from Germany to Barcelona. Nearly half of these were sick and wounded. The total number of prisoners of the British Commonwealth and Empire who would be repatriated under the present agreement was about 5,400. This number included about 170 sick merchant seamen and about 100 sick interned civilians. So far as he knew, every single prisoner eligible under the Geneva Convention was being repatriated in this exchange. He did not think that any man who had been passed by medical authorities would have been left in Germany. Between 5,000 and 6,000 German prisoners of war were being sent back to Germany by the British Commonwealth and the United States.

Representative Committee

Dr. RUSSELL THOMAS inquired on Oct. 21 how many doctors represented the medical profession in the recent negotiations in regard to the future of medical practice, and how many of these act or acted as members of any advisory or other committees or in any collective or individual capacity in connexion with the Ministry of Health or any other Department. Mr. ERNEST BROWN replied that a Representative Committee of 42 members was selected by the B.M.A. in collaboration with the Royal Colleges. His information did not enable him to answer the last part of the question exhaustively, but of the 42 representatives chosen by the profession, ten were also members of his Medical Advisory Committee. An additional three representatives assisted his Department as members of advisory committees or in an individual capacity.

Distribution of Doctors

In an answer to Mr. Henry White on Oct. 21 the MINISTER OF HEALTH said the Central Medical War Committee and its local committees, in selecting doctors to make up the quota required by the Forces, did their best to maintain an adequate medical service for the civilian population, but in some areas there must inevitably be a heavy burden on the remaining

EPIDEMIOLOGY SECTION

Nov. 6, 1943

vectors and some inconvenience for the public. For the areas
ost in need of help arrangements were being made through
e C.M.W.C., in accordance with a recommendation of the
Committee presided over by Sir G. Shakespeare, for employ-
ment of suitable doctors as assistants in general practice. These
ould be chosen mainly from those found unfit for service
the Forces, and the powers of direction under the Defence
regulations would be used so far as appropriate for this
purpose.

G.M.C. Representatives

Mr. HUTCHINSON asked on Oct. 21 why the Government had
vised His Majesty to continue unchanged for a fourth year
the composition of the General Medical Council, as provided
by the General Medical Council (Temporary Provisions) Order,
1943. Mr. ATTLEE said this Order related only to those members
of the General Medical Council elected by medical practitioners,
owing to continued absence with the Forces or on other forms
of national service of a substantial proportion of the electorate.
An election at present would present great practical difficulty
and would imperfectly represent the views of those entitled to
vote.

Equipment for Gas-and-oxygen Anaesthesia

On Oct. 21 Major C. TAYLOR asked what number of hospitals
dealing with maternity cases were equipped with gas-and-
oxygen anaesthetic appliances. Mr. ERNEST BROWN said 47
local supervising authorities in England and Wales provided
the apparatus, in some cases for domiciliary use. Of the 88
emergency maternity homes under the Government evacuation
scheme 60 had been supplied with machines for the administra-
tion of gas-and-air anaesthesia. He had no information as to
the provision of this equipment in voluntary hospitals.

Cholera and Deaths from Famine in India

Mr. AMERY stated on Oct. 21 that cholera had been reported
in various parts of India, but he had so far no indication of
any widespread outbreak, nor of special difficulties experienced
by Provincial Governments in dealing with outbreaks of this
or of any other disease. He had no recent report of shortage
of drugs or medical supplies for civilian use. As regards deaths
by famine, figures were incomplete and unreliable. In Calcutta
mortality was reported to be twice the normal for the time of
year. Between mid-August and mid-October about 2,000
persons suffering from malnutrition died in Calcutta hospitals.

Typhus in North Africa.—During last typhus season in North
Africa there were 20 cases among British troops, of which six
were fatal. No cases have been reported from Sicily during opera-
tions in that area. Some 30 cases of typhoid fever have been
reported from North Africa.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of scarlet fever and measles
continued to mount, by 75 and 94 cases respectively, while
decreases were recorded for diphtheria 25 and dysentery 10.
The largest local increase for scarlet fever was in Staffordshire
with 31 more cases, and for measles, in Norfolk, also with 31
more.

The total number of cases of dysentery is still high—253.
The largest of the new outbreaks was in Bedfordshire, Biggles-
wade R.D. 15. In Kent notifications fell from 59 to 12, and
in London from 52 to 46. Several areas recorded rises, impor-
tant centres of infection being Yorks West Riding with 26,
Lancashire 22, Middlesex 22, Somerset 19, Warwickshire 13,
and Leicestershire with 10 notifications.

In Scotland diphtheria went up by 31 cases, scarlet fever by
31, and acute primary pneumonia by 23; dysentery was down
by 34, and whooping-cough by 24 cases. The higher incidence
of diphtheria was confined to the western area; the rise in
scarlet fever and pneumonia was fairly general. Almost half
of the cases of dysentery were reported from the two cities of
Glasgow 14, and Edinburgh 13.

In Northern Ireland there were 23 more cases of scarlet
fever: 82 of the 118 notifications were recorded in Londonderry.
The principal centre of diphtheria infection was Londonderry
C.B., where 30 of the 37 cases occurred; this city is experiencing
the worst outbreak for ten years.

In Eire the incidence of diphtheria remained high with a rise
of 6 cases; 26 were reported in Dublin C.B. during the week.
The higher figure for scarlet fever was due mainly to an out-
break in Tipperary, Roscrea R.D. 14.

The Week Ending October 23

The notifications of infectious diseases in England and Wales
during the week included: scarlet fever 3,317, whooping-cough
1,459, diphtheria 725, measles 546, acute pneumonia 579,
cerebrospinal fever 46, dysentery 249, typhoid 7.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital
Statistics in the British Isles during the week ended Oct. 16.
Figures of Principal Notifiable Diseases for the week and those for the corre-
sponding week last year, for: (a) England and Wales (London included), (b)
London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

**Figures of Births and Deaths, and of Deaths recorded under each infectious disease,
are for: (a) The 126 great towns in England and Wales (including London)
(b) London (administrative county), (c) The 16 principal towns in Scotland, (d)
The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.**
A dash — denotes no cases; a blank space denotes disease not notifiable or
no return available.

* Includes primary form for England and Wales, London (administrative
county), and Northern Ireland.
† Includes puerperal fever for England and Wales and Eire.
‡ Owing to evacuation schemes and other movements of population, birth and
death rates for Northern Ireland are no longer available.

Medical News

A meeting of the Middlesex County Medical Society will be held at the West Middlesex County Hospital, Isleworth, on Tuesday, Nov. 9, at 2.45 p.m., when a clinical demonstration will be followed by papers by Mr. W. J. Ferguson on treatment of haematemesis and melaena in cases of recently perforated peptic ulcer, and Mr. D. M. Stern on treatment of stress incontinence in women. Visitors, including members of the U.S. and Canadian Forces now in this country, will be welcome.

A lantern lecture on "The Use of Plant Growth Substances" will be given by M. A. H. Tincker, D.Sc., at the house of the Pharmaceutical Society of Great Britain, 17, Bloomsbury Square, W.C., on Thursday, Nov. 11, at 7 p.m.

The London Women's Parliament is calling its fourth session on Sunday, Nov. 14, at the Bedford Theatre, Camden High Street, N.W.1. The object is to find how best to minimize the strain of war work while still maintaining production. Three subjects will form the basis for discussion: (1) Health in the factory, with special reference to hours worked, health committees, extension of welfare and medical care, ante-natal supervision. (2) Health in the borough, with emphasis on maternity provision, including more maternity beds, home helps, midwives, and maternity benefit; improvement of local health services, and a demand for a national health service as recommended in the Beveridge report. (3) Housing, with a demand for immediate control of all rents, including furnished premises, effective requisitioning of empty houses, billeting, repairs of houses, extended building programme, and an acceptance of the L.C.C. Plan.

The programme of lectures arranged by the Royal Institution, 21, Albemarle Street, W., includes two Friday evening discourses at 5 p.m.—one on Nov. 26 by Sir Joseph Barcroft, F.R.S., on the preservation of foods by drying, and another on Dec. 10 by Prof. H. W. Florey, F.R.S., on the development of penicillin for medical uses. A course of lectures on progress in the treatment of infections is being given by Sir Henry Dale, P.R.S., on Tuesdays, Nov. 9 and 16, at 5.15 p.m.; and at the same hour on Nov. 23 and 30 and Dec. 7 and 14 Prof. J. C. Drummond will give a course on food problems of the post-war years.

The names of Dr. Irene Marie Holden MacAdam, wife of Dr. W. MacAdam, professor of medicine at Leeds University, and of Dr. Joseph William Silversides, honorary secretary of the Leeds Joint Council of Industrial Medicine, have been added to the Commission of the Peace for Leeds.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Atiology Westcent*, London; SECRETARY, *Medisera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Cause of Cancer Cachexia

Q.—The wasting in malignant disease is far in excess of the extent of the growth, which suggests a toxæmia. Has a toxin been yet discovered?

A.—A toxin has not been discovered. The important known causes of cachexia are sepsis and interferences with organic functions, as, for example, by pressure or obstruction.

Rapid Loss of Hair

Q.—A man aged 32 complains that his hair is falling out at a prodigious rate. The baldness is "natural" in distribution, being situated over the crown of the head, and it has not the patchy appearance of alopecia areata. But the extreme rapidity with which it is being lost leads me to suspect an underlying factor. He has grown perceptibly balder in the two months I have known him.

The scalp appears normal, and the patient is in excellent health. There is no indication of myxoedema, but I wondered if small doses of thyroid extract might benefit the condition. At the present of loss he should be quite bald in six months. Up to four months ago his hair was extremely thick and strong. Could you advise as to any treatment, either local or general, that might benefit the condition; and also give me some idea of the possible cause?

A.—It is possible that the loss of hair described is the result of febrile illness—e.g., influenza—about two months before the hair was noticed. If this is the case the hair will almost certainly return satisfactorily in a few months. If there has not been illness, probably the trouble is a form of alopecia areata, in which case some "exclamation mark" stumps may be discovered. Small doses of thyroid are not likely to have any effect unless there is definite thyroid deficiency. Ultra-violet light, either locally to the scalp or general to the whole body once or twice a week, might be tried.

What to do with Diphtheria Carriers

Q.—Is it necessary to isolate every diphtheria carrier who has been discovered? As the number of immunized people rises, the number of carriers must rise, and isolation and cure will become a problem of much difficulty.

A.—The handling of the diphtheria carrier is a controversial subject. The procedure should vary according to (1) the environmental conditions, (2) the nature of the carrier state, and (3) the laboratory facilities available.

1. If a diphtheria carrier is discovered in a family or close community where there are other susceptible children, it is wise to remove the carrier until the other children have been protected by active or combined active-passive immunization. On the other hand, isolation of the diphtheria carrier in a day-school where a high proportion of the children have been immunized is probably unnecessary, particularly if the children are under regular medical supervision.

2. The carrier state is with many children a transitory phenomenon, and children with healthy mucous membranes in the nose and throat are not likely to be persistent carriers or to spread the infection. Thus, carriers discovered in the routine swabbing of contacts are often temporary carriers and should not be transferred immediately to an isolation hospital unless there is some clinical abnormality in the upper air passages. The diphtheria carrier with nasal discharge or diseased tonsils is more dangerous and should be isolated and treated. There is, of course, no power in England and Wales to remove a carrier as such from a hospital, but parents can usually be persuaded of the advisability of doing so. While a temporary increase in carriers in place of clinical cases might be expected as a result of immunization (this happened at Greenwich Hospital School), experience in Canadian and American cities has shown that after a high proportion of the children have been inoculated the carrier rate at them falls to a very low level.

3. The diagnosis of a diphtheria carrier is a joint responsibility of the physician and the bacteriologist. Swabs must be taken from both nose and throat and should be inoculated into tellurite-containing medium. Organisms resembling *C. diphtheriae* should be examined biochemically, and, if necessary, by a method of inoculation to find whether they are toxigenic. Unless this is done—and in many areas laboratory facilities are still inadequate for the purpose—no reliance can be placed on a report of the presence or absence of *C. diphtheriae*.

M.O.s and G.P.s

Q.—Some time ago I saw a statement that the Ministry of Health would be pleased if local authorities could allow public health medical officers in their spare time to help out the general practitioners who are at present being overworked. I would be pleased if you could let me know when and where the statement was made, and whether the local authorities were circularized concerning it.

A.—In the House of Commons on May 20, 1943, Major I. (Leicester E.) asked the Minister of Health if he approved arrangements whereby, in the present call upon medical practitioners, medical officers, both men and women, holding appointments with local authorities voluntarily agree to assist in the work at hospitals and general practices in cases of special urgency; and whether he would consider taking steps to encourage this type of arrangement in present circumstances. The Minister of Health replied: "I am glad to learn of any co-operative arrangements between medical practitioners which will help to relieve the pressure on the public at the present time, but owing to the great variation in local conditions I do not think that I could usefully commend any particular scheme for this purpose." Major Lyons continued: "While recognizing the difference in local conditions, may I ask whether the hon. gentleman would let local authorities know that where possible this kind of co-operative effort meets with his approval?" Mr. Brown replied: "I think that they know that, and this question will serve to spread the light further."

Sedimentation Rate

Q.—What is considered the normal erythrocyte sedimentation rate? What is the significance of a raised rate? Does it always indicate a chronic infection? If a raised E.S.R. be found by chance in an otherwise symptomless patient, what notice should be taken of it?

A.—The normal erythrocyte sedimentation rate varies with the method used. With the Westergren method a reading of 3 mm. in one hour is normal, 4 to 6 mm. is doubtful, readings between 7 and 12 mm. are probably abnormal, and higher readings are certainly pathological. With the Wintrobe method the normal sedimentation reading is 3 to 4 mm. plasma at one hour for a man, 9 to 10 mm. or less for a woman. A raised sedimentation rate does not always mean a chronic infection. It occurs also in acute infections, in pregnancy, in anaemia, in malignant disease, in acute uterine or coronary thrombosis, etc. Menstruation does not increase sedimentation rate in health.

If a raised sedimentation rate is found in an otherwise symptomless patient, the test should be repeated in a month's time. In the meanwhile the patient should be thoroughly examined clinically, a good count made to see if there is any anaemia, and the chest x-rayed to exclude, so far as possible, pulmonary tuberculosis. An increased sedimentation rate indicates a pathological state, but very rarely a normal sedimentation rate is found in active pulmonary tuberculosis.

Short Stature and Endocrinology

Q.—Apparently experimental endocrinology has been successful in producing gigantism in animals by the administration of a pituitary growth hormone. I have a patient who is worried because of two children, aged 4 and 6 respectively, are shorter than is normal for their age. The mother and her family all tend to be of short side. The mother is anxious to know whether available pituitary preparations could be used to accelerate the rate of growth, and whether this could be carried out without any risk to the patient. The home conditions are satisfactory and the children are well fed. I of course assume that any course of treatment would be under the direction of an endocrinologist.

A.—The pituitary growth hormone to which the questioner refers is available for treatment in man. Of one variety 2 c.c.m. or more can be injected intramuscularly three times a week for a period of six weeks, and then repeated after an interval of a month. The results are variable and often disappointing. Desiccated thyroid can be given alone or in conjunction with this treatment to the point of tolerance. Testosterone may also produce an increased rate of growth, but must be administered with caution in young children. As regards the possible risk in using pituitary growth hormone, local reactions are not infrequent, and occasionally a general reaction of an allergic character may occur.

Night Frights in an Adult

Q.—A physically healthy man of 25 has had night frights since the age of 18. They may occur once or several times a night for weeks on end, or they may not occur for a similar period. In a mild fright he shouts out, "No, no, no," but in a severe one he awakes at the top of his voice and tries to escape from the room either through the door or window. He is a highly strung person and is energetic. He has stammered since childhood. He has a responsible position in a business firm. Bromides and phenobarbitone have been tried with only slight improvement. I should like to know: (1) Is the cause likely to be a single repressed incident occurring in childhood? (2) What are the chances of success from expert psychotherapy? (3) Can some idea of the length of treatment necessary be given?

A.—The clinical details given in the question are insufficient to permit of more than a tentative answer.

Point 1.—It is unlikely that a single incident can be the cause of the dissociative nightmare attacks. These night frights must be regarded as a break-through of a "screen-memory," only partly expressed. Such incidents which appear in the analysis of psycho-neuroses have the function of partly concealing and partly expressing the underlying predisposing conflicts in highly condensed form, symbolizing what is typical for the emotional problem. Only the full recall and analysis of the contents of these attacks can reveal the deeper causes. It is, however, safe to assume that these lie in early relationships with other people. That such relationships were not smooth is shown by two important details—the stammer and the "highly strung energetic" personality. Owing to some undisclosed present-day stress repression has failed; the emerging primitive feelings (no longer sufficiently held in check by the old defences of stammer and tense active attitude) seize upon some old or even recent "incident," which is also likely to possess significance in its own right. Often, however, such incidents are found to exist only in fantasy, which does not diminish their importance in psychotherapy.

Points 2 and 3.—The chances of successful psychotherapy are high. An acute symptom provides a strong incentive for the patient's co-operation and a ready-made portal of entry to the

problem for the therapist. The terror attacks are thus likely to be resolved quickly as psychiatrists count time—e.g., in ten to fifteen sessions, with one or two applications of light hypnosis or evipan narcosis as a possible time-saving technique. At this stage the patient may wish to stop, full of gratitude for his temporary relief, but with the deeper problem probably unsolved. It is likely that the emotional trends released by reduction of the acute symptom will make themselves felt in either new symptoms or behaviour. Ideally, therefore, a longer period of treatment is called for. The patient may be glad to follow on if his circumstances and his psychological insight permit. This phase of treatment may last six months or more of regular analytic sessions. Even then, traces of stammer are likely to persist, although they will have lost much of their subjective importance. A constitutional element may be present. On the other hand, for practical purposes, in wartime especially, the short treatment only resolving the urgent symptom may have to suffice. Any expert would, however, take tactful steps to warn the patient that the job was incomplete, but that further help was possible if new discomforts should develop with which the patient could not cope unaided.

Gynaecomastia

Q.—What are the aetiology and treatment of gynaecomastia? What are the prospects of malignant change occurring? The patient is in the late thirties and he has had the condition for about two months. Previously quite normal and absolutely no evidence of hypogonadism. On page 442 of the JOURNAL Dr. J. C. Jones recommends stilboestrol, while on page 403 Dr. Magee points out that stilboestrol will of itself produce the condition. The statements appear to be contradictory. Furthermore, Lacassagne has repeatedly induced mammary carcinoma by injections of oestrons in the male. In the present instance the patient only returned from the Middle East about three months ago and there is an admitted history of sexual excess, without, however, any apparent loss of power. He has acquired the habit of taking occasional doses of iodine as a "tonic."

A.—The causes of gynaecomastia are still hypothetical, and authorities differ profoundly. The breasts are bisexual organs, which develop in girls under the influence of the female sex hormones, but not in boys, in whom the small amount of female sex hormone is more than cancelled by the production of male sex hormone. It would appear from this that the development of breasts in men could be brought about either by an increase in circulating oestrogens or a decrease in circulating androgens. There must also be considered, however, the response of the breast tissue, which is probably genetically determined. It is conceivable that in some individuals the responsiveness of the breasts to oestrogens is so great that normal circulating androgens are powerless to counteract their effects. This undue sensitivity may be due, as some believe, to a weakness in the original genetic "urge" to masculinity, for sometimes gynaecomastia is associated with other signs of mild intersexuality. The occasional occurrence of unilateral gynaecomastia is not, on this hypothesis, surprising, for an unequal response of the two sides to hormones is often seen: the breasts of a normal woman are often of unequal size, and unilateral acromegaly has been reported. This hypothesis explains the intersexual cases, those which have occurred in factories where oestrogens are manufactured, and those associated with atrophy of the testicles.

Bearing in mind that oestrogenic substances are probably produced in the testicles and adrenals, it explains the cases which have occurred in association with neoplasm of the testis, teratoma generally, and chorion epithelioma, and in Addison's disease under treatment with adrenal cortical extracts. Nevertheless it is not suggested that the hypothesis is complete. It does not, for instance, take account of the possible influence of progestational hormones in the production of some cases. I have seen the condition twice in association with mental disease, a relationship which suggests a possible diencephalic origin. No medical treatment is effective. Methyl testosterone by mouth, a rational method, has proved disappointing. Stilboestrol makes the condition worse, and, as the question suggests, may be a common cause. There appears to be no special predisposition to malignant change, but as the sight of his breasts usually depresses the patient it is advisable to remove them.

Epidermolysis Bullosa

Q.—For about nine months, from the time of the infant's birth, I have been watching a case which corresponds accurately with Hallam's description of epidermolysis bullosa ("Brit. Ency. med. Pract." vol. 5, p. 82) of the simple uncomplicated type. A large blister was present at birth; there were lesions present suggestive of ante-natal blistering, and the trouble still persists. Otherwise the child is very healthy. There is no history of other skin trouble in the family. We have treated the lesions with zinc oxide, starch, and boric powder, and they have healed quickly and well; but as the time approaches when the child will begin to walk, the anxiety to secure a cure, if such is possible, increases. At present even very slight rubbing results in blister formations, especially on the

feet and forearms. I shall greatly appreciate any suggestions as to treatment.

A.—There is no known treatment for epidermolysis bullosa which can be relied on to do good. Arsenic in small doses over a long period is sometimes advised. When the patient is the product of a consanguineous marriage, blood transfusion from a donor outside the family has been suggested. But in the case described it does not sound as though either of these treatments was likely to be practicable, and reliance will probably have to be placed on protection from trauma and local treatment to the lesions as they arise.

Too Much Liver

Q.—Is it possible to inject too much liver extract, and if so, what are the symptoms?

A.—Apart from hypersensitivity and gout, there is no evidence of toxic effects from large doses of liver extract by injection. Amounts of 160 c.cm. have been injected intramuscularly in one week in pernicious anaemia without ill effect in the endeavour to produce a long remission: this hope, by the way, was not realized. In the treatment of sprue 20 c.cm. of liver extract has been injected intravenously every day for a fortnight and then twice weekly, again without any ill effect, and with marked benefit to cases which had resisted less strenuous treatment.

Vitamin A and the Cornea

Q.—In minor lesions of the cornea—e.g., abrasions, removal of superficial foreign bodies, etc.—is it of any advantage to instil cod-liver oil (in virtue of its vitamin A content) in place of the customary oil ricini?

A.—There is no valid evidence that the local application of vitamin A has any effect at all.

The Barometer and Blood Pressure

Q.—A drop in the barometer reading of 2 in. means a drop of 50 mm. of mercury. No account of the barometer reading is taken when a patient's blood pressure is being examined. Why is this? Does it make no difference to the reading?

A.—Changes in the barometer make no difference to the patient's blood pressure as read with the ordinary blood pressure apparatus. It is true that the absolute pressure in the artery does change with changes in the barometer, but since the tension of the arterial wall and tissues balances the arterial blood pressure against the given atmospheric pressure and not against a vacuum, the absolute blood pressure does not seem to be of much clinical significance. As ordinarily read, the atmospheric pressure is the same on both sides of the mercury manometer, and therefore cancels out.

Home-preserved Meat

Q.—The preservation of fruit has become a very simple and very popular household job, and some housewives would like to preserve meat in a similar way in order to use it when it is wanted most. Would the following method be effective and devoid of any risks of food poisoning? The meat is cooked in its own juices in the usual way. Then it is transferred with its liquid surroundings into a Kilner jar. This is heated to form a vacuum, and the meat preserved in an airtight partial vacuum as for fruit.

A.—The home preservation of meat is decidedly much more difficult than for fruit. The degree and times of cooking of foods in glass or other containers to render that food safe from the risks of conveying disease depend on a number of factors, including the acidity of the food, the size of the containers, the temperature at which introduced, and, in particular, the rate of heat transfer through the food. For example, with acid foods (such as most fruits) less heat is required than for meat. With a largely solid food, such as most forms of meat, heat penetration is mainly by conduction, and not by convection, as in fruit, and as such is relatively much slower. These factors add to the difficulty of any satisfactory home sterilization for meat products.

The question assumes that the meat is cooked before introduction into the jar, but it has to be remembered that penetration in ordinary cooking is slow, and numerous experiments demonstrate that the interior of meat rarely reaches temperatures adequate to destroy pathogenic bacteria, and cannot be relied upon to destroy either *Salmonella* strains or *Clostridium botulinum*. In dealing with meat eaten fresh this is not of much practical importance, but with preserved meat, unless the subsequent heat treatment is effective, any such surviving bacteria would multiply and heavily contaminate the product, and be a possible source of food poisoning. In commercial meat canning, although the meat is cooked before introduction into the can, temperatures of about 120° C. are employed, the time varying with different factors, including the size of the can. This involves the use of pressure cookers. Such sterilization with temperatures well above boiling-point is very different from domestic heating in a Kilner jar, when the maximum temperature cannot rise above 100° C. In the early days of commercial meat canning temperatures of 100° C. were commonly employed, but were found unreliable and led to food spoilage.

The above considerations suggest strongly that the home preservation of meat products in Kilner or other similar jars is an unsafe procedure and one not safe from the risk of the meat being a vehicle for the conveyance of food poisoning.

INCOME TAX

Purchase of Share in Practice by Instalments

W. J. is about to buy a share in a practice paying for it on instalments. Would such annual payments be allowed as deductions?

* No. The transaction is of a capital nature and the payments do not affect the income-tax liability either of payer or receiver.

Professional Expenses

"I. R. Q." inquires whether the cost of repairing a watch—“a necessary instrument in my practice”—is an allowable expense.

* An expense is not necessarily allowable because it is professional work to be carried on—i.e., the attire of a solicitor may be more costly than that of his country colleague or a tradesman, but would not in our opinion give rise to a valid claim for allowance. On the other hand a watch is used daily in medical work, and some proportion of the repairing cost may be claimable on that ground; but we doubt if an appeal would be worth while.

Board and Lodging

W. B.'s salary is £360 per annum and board and lodgings are provided. He has been assessed on £438—i.e., £360 plus 78s. which represents 30s. per week. Is that correct?

* If, as appears to be the case, the contract of employment provides for a salary of £360 and for free board and lodging, the liability is on £360 only. (If the contract provided for a salary of £438, of which £78 was to be satisfied by provision of board and lodging, leaving the balance of £360 payable in cash, the tax liability would be on £438.)

LETTERS, NOTES, ETC.

Menorrhagia and Thyrotoxicosis

Mr. E. G. SLESINGER (London, W.1) writes: I was surprised to see in the *Journal* of Oct. 25 (p. 533), under the heading "Menorrhagia and Hyperthyroidism," the statement, "Menorrhagia is uncommon in thyrotoxicosis," followed by the suggestion that local pelvic disease and blood disorders had been excluded. Menstrual disturbance should be regarded as another symptom of the thyroid dysfunction. In many years' experience of thyrotoxicosis I have never seen a case of menorrhagia due to thyrotoxicosis, nor do I believe that such a connection occurs. The point in question may well be thyrotoxic, but I feel sure the menorrhagia is due to some other cause, and that if thyroidectomy were needed because of her thyrotoxic state it would not of itself cure the menorrhagia.

Resuscitation by Rocking

Colonel P. J. RYAN (A.D.M.S. Headquarters) writes: Recent articles and correspondence in the *Journal* refer to various methods for "rocking" in the case of an individual apparently drowned. It is suggested that, when available, a wheeled stretcher apparatus such as is in use in the British Army, could be used with advantage for the rocking method of resuscitation. Such an apparatus depicted in your issue of May 22 (p. 648) and a similar one in your issue of May 1 (p. 542). The patient should, however, be lashed on to the stretcher face downwards with arms extended and checks placed against the wheels to steady the apparatus. A minimum of two men is required to rock this apparatus.

Transfusion into Bone Marrow

Dr. A. PINEY (London, W.1) writes: A warning is needed to amplify the answer to the question about transfusion into the bone marrow (Oct. 9, p. 471). Sternal infusions are impossible in case of infants because there is no medullary cavity in the sternum. Even by the age of 3 years there is very little marrow in the bone; and it is not until 7 or 8 years of age that infusions are possible. If the tibia is used for infusion in an infant, the point of the needle must be downwards—i.e., towards the epiphysis and away from the knee, so that there is no risk of damaging the epiphysis. Finally, those who are not experienced with the technique should be told that, even when the needle is properly in the medullary cavity of the sternum, the initial rate of flow of the infusion fluid is slow—e.g., about 4 c.cm. a minute—but at the end of about five minutes the rate increases and fluid can be infused as fast as may be desired.

Correction

The sentence beginning in the eighth line from the bottom of the second column of the leading article at p. 549 in the *Journal* of Oct. 30 contains an obvious error. It should read: "But this does not preclude . . ."

THE COMPREHENSIVE ATTACK ON PULMONARY TUBERCULOSIS*

BY

Sir ARTHUR S. MacNALT, K.C.B., M.D., F.R.C.P., F.R.C.S.

A Vice-President of Papworth Village Settlement; A Member of the Institution of King Edward VII Sanatorium

"When good men die their goodness does not perish
But lives though they are gone,"

wrote Euripides. We have come together to-day to do honour to one of the world's benefactors, to pay a tribute to a man who was great and single-hearted, who was not content with deploring the sad lot of the consumptive but used his scientific and intellectual gifts to find a solution to the problem, and, in spite of much misunderstanding and even veiled opposition, succeeded by the very force of his character and genius.

Before turning to the ways in which the social and economic aspects of the tuberculosis problem can be approached I will devote the first part of this lecture to a consideration of certain principles which should guide the physician in the treatment of pulmonary tuberculosis. They are important and fundamental ones. They have been inherent in the practice of famous institutions, like the Brompton Hospital for Consumption and King Edward VII Sanatorium at Midhurst, for many years with great success. But I regret to add they are often either neglected or are unknown to many entrusted with the treatment of consumptives. We have not enough Professors of Tuberculosis in our universities or lecturers on that subject in our medical schools to teach the lessons of clinical experience to medical students.

Residential Treatment of the Consumptive

A considerable degree of confusion still exists as to the appropriate use of hospitals and sanatoria and their interdependence in the treatment of persons suffering from pulmonary tuberculosis. It is highly important to realize, first, that there is a great distinction between hospital and sanatorium treatment, and, secondly, that, while this distinction obtains, the two forms of treatment are complementary to one another. A patient after a period of hospital treatment may become suitable for sanatorium treatment; a patient in the course of sanatorium treatment may regress and require hospital treatment. This right use of residential treatment is so frequently ignored, with disastrous results to the patient, that it cannot too often be reiterated. Many local authorities, and even some of their medical advisers, are under the impression that all persons suffering from pulmonary tuberculosis, if diagnosed early enough, will recover with prompt sanatorium treatment. If discovered, many early cases do obtain arrest in this way, although there is a florid type of pulmonary tuberculosis that proceeds to a fatal issue however early the diagnosis and however skilled the treatment; whilst other patients under sanatorium treatment pass into the intermediate or advanced type of the disease and stand in need of hospital treatment.

But the early case is a *rara avis*, especially in a working-man who cannot afford to be one. As Varrier-Jones, with whom I often discussed this problem, wrote:

"Hitherto few, if any, so-called 'early' cases have been truly early, and the sooner this depressing fact obtains general recognition the sooner we shall begin to make some progress in the sphere of prophylaxis."

* Being the Second Varrier-Jones Memorial Lecture, delivered at No. 10 Canadian General Hospital to members of the Royal Canadian Army Medical Corps on Aug. 26, 1943.

Great hopes are built now upon routine mass radiography for the diagnosis of the early case. Far be it from me to belittle these hopes. In skilled and expert hands the results obtained by Dudley and Fitzpatrick, by Surg. Capt. W. D. W. Brooks, and by Wing Commander Trail already testify to the success of this method in detecting previously unsuspected cases. Trail observed, in the first of these lectures, that some 25% more cases are found in the early stage of mass radiography than by the present civilian methods of diagnosis. But in the use of x rays for diagnosis Varrier-Jones gave a word of caution which is especially timely to-day. This is what he said:

"When we take an x-ray film we are filled with wonder at the complications of nodes and shadows, not sufficiently realizing that what we are gazing at is the picture of past battles, filled-in trenches, exploded mine-craters, and the like. What we imagine we see, but do not, is the advancing army of disease. . . . We have interpreted the x-ray film wrongly. Instead of using it as an index of equilibrium (which as a rule is impossible) we have used it as a picture of the present battle, whereas it is but the shadow of past conflicts."

X rays, then, are a valuable adjunct, but only an adjunct, to the diagnosis of active pulmonary tuberculosis. They do not provide a rule-of-thumb diagnosis or indicate the appropriate treatment. The physician and the radiologist must work together in this matter. It should also be remembered that many extensive and intermediate cases of pulmonary tuberculosis, and even cases classed as advanced, after efficient hospital treatment, often combined with collapse therapy and surgical measures, may become suitable for sanatorium treatment and attain complete quiescence of their disease. The unfortunate heresy that all cases of pulmonary tuberculosis are suitable for sanatorium treatment is only gradually disappearing from our midst.

Tuberculosis is a protean disease. Its manifestations have to be studied in the individual patient, and that study must be based upon clinical experience. The treatment given must be adapted to the present needs of the individual patient. A stereotyped treatment which automatically puts patients with early physical signs into sanatoria and others into hospital meets with inevitable failure. No man has appreciated this teaching more than Varrier-Jones. He applied it with marked success to the treatment of patients at Papworth.

Selection of Patients for Different Forms of Treatment

From an examination of a number of patients suffering from pulmonary tuberculosis the physician finds that they can be relegated to the following categories:

At the time the disease is recognized a certain proportion of patients are suitable for sanatorium treatment forthwith (i.e., in the strict and limited sense previously mentioned). A second, and larger, proportion of patients will require a period of initial treatment either in a tuberculosis hospital or in the nursing block of a sanatorium before they are suitable for strict sanatorium treatment involving occupational therapy. The rest of febrile patients should be "absolute," not only in name but in practice. A third proportion of patients are suitable for treatment in a tuberculosis hospital. Some of them are unlikely to derive benefit in the future from strict sanatorium treatment; but after collapse therapy or surgical treatment—e.g., thoracoplasty—many will have their lives

prolonged and be able to work under sheltered conditions. In the remaining group of patients the disease at the time of examination is too advanced and extensive for sanatorium treatment; palliative treatment, either in the tuberculosis hospital or at home, is required.

In most cases it is desirable to keep the patient for a week or so in an observation ward before deciding on the form of treatment most suitable for his individual case.

The principles which guide the physician in the treatment of pulmonary tuberculosis may be summarized as follows:

1. The diagnosis of pulmonary tuberculosis at the earliest possible stage, as well as the careful examination, including x-ray, of all contacts, especially adolescents and young adults.
2. A proper selection of patients for sanatorium treatment.
3. Full co-ordination between the tuberculosis officer or medical practitioner and the medical superintendent of the hospital-sanatorium.
4. Correct co-ordination of hospital and sanatorium treatment.
5. Study of the individual patient.
6. A proper hospital and sanatorium regime.
7. Prolonged duration of stay in the sanatorium.
8. The goal to be aimed at is the discharge of the patient with the disease quiescent and in a fit condition to resume an occupation.

To these principles should be added the maintenance of the ex-sanatorium patient, in whom the disease has become quiescent, under medical supervision for at least five years, the injunction to seek medical advice at the first symptom of renewed ill-health, residence in a village settlement, or, if this is impracticable, suitable after-care provision by the local authority.

If these principles were generally practised throughout the country the sanatorium results of every local authority would be as favourable as those already obtained in the sanatoria of the more progressive authorities.

The Principles of Papworth

I have dwelt at some length on the principles of right treatment because they are inseparable from the work of him whom we honour to-day. Efficient treatment of the consumptive is the core of Papworth. This medical aspect of the village settlement is too often overshadowed by its industrial triumphs. Yet the two aspects are inseparable. As Varrier-Jones said:

"Papworth has proved quite definitely that when the teaching of the medical profession as to tuberculosis can be put into operation the results are exactly those which were anticipated. The progress of disease can be 'arrested' and the condition of 'arrest' can be almost indefinitely prolonged."

We know that with efficient modern treatment, in favourable conditions the consumptive can obtain arrest of his disease and eventually return to play his part in the workaday world. There are many men and women to-day doing useful work who have at one time suffered from active pulmonary tuberculosis. In their case the conditions were favourable, and they survived the critical five years that follow arrest of the disease. But this satisfactory condition of affairs does not obtain with the vast majority of "arrested" patients who return as damaged lives to compete with healthy labour. "The economic world will not support an unearning unit." "The consumptive man's resistance power breaks down under the strain. Often he has given hostages to fortune and has to support a wife and family. Even as the working-man cannot afford to become an early case of tuberculosis, so in the same way he struggles to carry on when the strain of occupation has caused a recrudescence of his disease. Then, inevitably, he is forced to give up the struggle. But when he comes once more under medical treatment the tubercle bacillus has made headway and there is far less chance of recovery.

As tuberculosis officer in Cambridge at the beginning of the last war, Varrier-Jones pondered on these disheartening results and sought a solution. He found it in the scheme which he started at Bourn in 1916. It began in a small way. On the site a few shelters were erected and the patients installed. In the house resided a matron, a nurse, and a cook. Before Varrier-Jones died in 1941 he saw this nucleus develop into a great institution at Papworth with 1,000 acres of land, administrative blocks, hospital blocks provided with every facility for

modern treatment, a large sanatorium section, laboratories research institute, a village settlement of nearly two hundred cottages, hostels for men and women, and factories equipped with labour-saving machinery and operated on a production lines. This means an incentive in life to the patient and an economic future.

Here, then, at Papworth is embodied the secret of successful treatment of tuberculosis. Of primary importance is the fact that the consumptive remains under continuous supervision medical, psychological, and social. He passes through stages of hospital and sanatorium treatment and is provided with occupation suited to his state of health. When afebrile he works at a trade, for which he receives the trade union rate wages. He resides in a hostel or, if married, in the village settlement with his wife and family. If at any time his health relapses he is sure of prompt and expert treatment in institution.

Papworth and the Prevention of Tuberculosis

Hitherto we have considered the work at Papworth from the curative and remedial standpoints. Varrier-Jones points out that tuberculosis colonies also play an important part in the prevention of the disease. Let me quote his own words on this subject:

"The fatal 'mass' dose, so common yet so unnecessary, does not occur in village settlement conditions. So far it has been avoided at Papworth. Our experience in this respect seems to show that a village settlement can cut the vicious circle of infection which spreads the disease all through whole families. What does this imply? If anything, it means that here we have a means of reducing tuberculosis to the incidence level of smallpox, it means that, in the long run, it is far cheaper to establish a family in a settlement than to send each of its members, after another, from sanatoria to their homes to spread infection. There is a mass of evidence to prove this. On the other hand, patients discharged to a village settlement need not spread infection. These facts alone justify village settlements on human as well as financial grounds, but it is most difficult to make people understand and admit this."

Varrier-Jones had the question of contact examination in mind from the beginning of his project. He was quick to realize that in the village settlement he had a unique opportunity for studying this problem. The settlers and their families could be kept under continuous medical observation. X-ray and laboratory technique were available to supplement the findings of the expert clinician.

The organized work began as far back as 1921. Under Pendrill's direction it was entrusted to Dr. L. B. Stott. In visits to Papworth I have been able to see the progress of work, at which Dr. Stott laboured with unremitting zeal and energy over a period of many years. Before his death Varrier-Jones arranged that Dr. Brieger should examine and collect the vast material which Dr. Stott had prepared. I must anticipate the detailed results of this prolonged investigation which are shortly to be published. Preliminary communications have appeared, and it has already been stated that one of the children born in Papworth village (and some have a considerable age) has, while a member of the community, contracted tuberculosis of the lungs, glands, bones, or joints indeed, in any known clinical form. There has been no case of tuberculous meningitis. Those who have left the settlement to seek education or employment elsewhere are all free from the disease. The x-ray findings indicate that an appreciable proportion of the children have been infected by tuberculosis like the rest of us: If the hypothesis of reactivation of tuberculous infection contracted in childhood be accepted, cannot be said that none of these children will develop pulmonary tuberculosis in after-life or that they may not be exposed to superinfection. Nevertheless, not a few of the children have passed through the susceptible stage of adolescence without showing signs or symptoms of pulmonary tuberculosis, and it is not improbable that this resistance to disease may be maintained throughout life. Adequate food supply, instruction in dietetic values, assured employment with no risk of unemployment after breakdown, freedom from anxiety, proper housing and hygienic precautions help to account for these remarkable results. Alone, without the many other beneficial features which I have described, they would justify the principles of village settlement.

Rehabilitation of the Consumptive after the War

At the end of the war we shall be faced, as we were in the last war, by a still greater incidence of pulmonary tuberculosis and an increase in the foci of infection. The approximate mortality figures are as follows: In 1939 the deaths from pulmonary tuberculosis in England and Wales were 22,000 (war conditions prevailed in only a little over three months of that year). In both 1940 and 1941 the deaths had risen to 24,000. Fortunately, in 1942 they dropped to 21,000, a decline which, it will be noted, has coincided with a lull in enemy bombing attacks on this country. Notifications of pulmonary tuberculosis, as is well known, form an imperfect guide to the incidence of the disease, as so many cases are reduplicated. It has been estimated from the latest available figures that the numbers of the adult population suffering from pulmonary tuberculosis in Great Britain at Dec. 31, 1938, was nearly 140,000. Of this total about 70,000 were classified as being able to return to ordinary employment, while about 20,000—most of whom were undergoing treatment in hospitals and sanatoria—were regarded as unlikely ever to return to any form of employment. In the remaining 50,000 the disease had been arrested or had become quiescent, and there was good prospect of achieving full recovery provided that special measures of rehabilitation were made available.* These are pre-war figures; wartime conditions have intensified the problem, and the number to be dealt with in the post-war period will show a considerable increase. Since the onset of war some advance has been made by the inclusion, under the Ministry of Labour's Scheme for Training and Resettlement of Disabled Persons, of quiescent and sputum-negative cases of tuberculosis in which the individuals are reintroduced into whole-time employment under ordinary industrial conditions (Ministry of Health Circular 2576, Feb., 1942). This, however, fails to meet the needs of those ex-patients for whom a slow and graduated resumption of work under medical supervision is required.

Varrier-Jones's pioneer work was partly inspired by the needs of tuberculous ex-Service men in the war of 1914-18, and in the present war the same problem arises. It is more and more becoming recognized that he found the true solution. The Medical Research Council's Committee on Tuberculosis in Wartime issued a report in 1942, which refers to the fact that the Papworth and Preston Hall village settlements have demonstrated one possible solution of the industrial problem provided by the chronic active case of pulmonary tuberculosis. The important Interdepartmental Committee's Report on the Rehabilitation and Resettlement of Disabled Persons devotes special attention to pulmonary tuberculosis, and states:

"Perhaps the most complete type of care for the tuberculous person and his family is the combination of sanatorium and hospital treatment with a village settlement."

In accordance with the recommendations of the Medical Research Council's Committee the Government has recently provided special maintenance allowances for patients suffering from pulmonary tuberculosis (Memo 266T of the Ministry of Health, April, 1943). This enables these affected persons to give up work for a while and receive treatment. The allowances apply to everyone undergoing approved treatment. They are administered by tuberculosis authorities as part of local health services, and comprise "maintenance allowances" based on a standard scale and without any test as to means, to which can be added, at the discretion of the authority, extra grants or special payments towards commitments. For the first time official recognition is given to the fact, so often urged by Varrier-Jones, that economic circumstances again and again prevent the consumptive worker from seeking residential treatment for his disease.

Now village settlements are few and, in my experience, local authorities are reluctant to embark upon them, although the Nottinghamshire County Council, which established the Sherwood Village Settlement in 1936, is a notable exception. In 1919-20 Varrier-Jones, the late Dr. Nathan Raw, M.P., and I constituted a small Departmental Committee which explored the question of establishing village settlements for ex-Service men throughout England and Wales. In the end it was con-

sidered better to develop the existing settlements at Papworth and Preston Hall than to provide new organizations. It is extremely probable that a committee of this character to-day would reach a similar conclusion.

In 1936 Varrier-Jones advocated the setting-up of a national board in order to co-ordinate the planning of a national rehabilitation scheme. This was endorsed by the late Lord Willingdon and the Joint Tuberculosis Council. The Medical Research Council Committee now favours the establishment of such a board. In view of the demands which will assuredly be made for village settlements and rehabilitation of the tuberculous ex-Service man at the end of the war, this board's work and direction seem to be urgently required.

Conclusion

In this lecture I have endeavoured to describe the great contribution which Pendrill Varrier-Jones made towards combating tuberculosis, and its comprehensive character. In the brief time at my disposal I have been able to give only an outline of the many agencies which he employed. I have not told, for instance, how he arranged for the psychological treatment of certain of his patients. Indeed, different phases of this pioneer work pursued untiringly for many years would supply a wealth of material for many lectures. He faced much opposition; he crossed swords with those who preferred the ways of routine and established tradition. In the end he triumphed and had the satisfaction of knowing that his principles were sound—for, contrary to common belief, he had the humility of the true scientist in all his investigations—and that they had stood the tests of time and experience and were becoming generally accepted.

"Unto each man his handiwork, unto each his crown,

The just Fate gives;

Whoso takes the world's life on him and his own lays down,
He dying so, lives."

"Seeing death has no part in him any more, no power

Upon his head;

He has bought his eternity with a little hour,

And is not dead."

So Pendrill Varrier-Jones took upon him the consumptive's burden and made it easier to bear. He died too early, but his works do flourish and follow him.

NOTE.—The quoted passages from Sir Pendrill Varrier-Jones's published papers in this lecture are taken by kind permission of Mr. Peter Fraser, Sir Pendrill's literary executor, from *Papers of a Pioneer, Sir Pendrill Varrier-Jones*, collected by Peter Fraser, London, 1943. ACCELERATION OF CO-ORDINATED MUSCULAR EFFORT BY NICOTINAMIDE

PRELIMINARY REPORT
TO THE MEDICAL RESEARCH COUNCIL*

BY

I. M. FRANKAU, M.D.

(Psychological Laboratory, Cambridge)

This report summarizes the results obtained from a series of experiments undertaken to demonstrate by means of a selected test the effect, if any, of certain vitamins on the physical efficiency and the fatigability of healthy young adults. Increased resistance to fatigue, or increased muscular ability, as a result of the addition of certain vitamins, especially B₁, to the diet has been reported by a number of observers. Others have failed to show, either in brief extreme exercise or in prolonged severe exercise and semi-starvation, indications of any effect of the vitamin supplementation to the U.S. Army rations on muscular ability, endurance, resistance to fatigue, or recovery from exhaustion. The present series of experiments, extending from April to December, 1942, tend to show that the addition of certain vitamins to the normal diet of healthy young men generally results in varying degrees of increased efficiency in carrying out a fairly severe test involving

* Report of Interdepartmental Committee on the Rehabilitation and Resettlement of Disabled Persons. Cmd. 6415, 1943, p. 11.

both physical efficiency and co-ordination. The experiments recorded in this report, with the exception of the Stanmore group, were carried out on selected personnel of the R.A.F.—air-crew cadets—who were in excellent physical training. The actual tests necessitated the utmost co-operation from the subject; without this co-operation no results of any value could have been obtained. The condition of the subject at the end of the test and his performance during the test were carefully noted, and in addition pulse rates were recorded at varying intervals.

Preliminary Tests

The test chosen was a modified form of the W.O. agility test. This test involves running rapidly, bending and turning quickly, and dropping disks accurately on a closely fitting shaft. No undue emphasis was laid on either accuracy or speed in describing the test to the subject, but the importance of finishing "flat-out" was stressed.

Four groups of young men from the I.T.W., ranging in age from 18 to 32, were tested on several occasions. They were extremely co-operative. The average time score for the first test was 60.75 seconds, and for the second 56.69 seconds. The difference between the time scores of the first and second tests was marked and relatively constant. There was little difference between the scores of the second, third, and subsequent tests; the second test was therefore adopted as the control test. There was very little scatter either in any single group or in the groups considered as a whole. In less-selected groups, such as civilians or the Home Guard, the time scores were found to vary considerably both from time to time and from subject to subject.

Modification of Test

It was obvious that this test in its original form would not produce any measurable degree of fatigue in subjects who were as physically fit as the I.T.W. Increasing the number of disks from 16 to 24 raised the average time score to 85.62 seconds; the time taken to complete 8 rounds (the original test distance) remained unaltered. Consideration of the clinical condition of the subject in conjunction with the time scores indicated that the test was still not severe enough. The effect of multiple vitamin tablets given to a small group who were retested was neither marked nor constant.

The distance of the test was finally increased from the original 170 yards to approximately 300 yards. In addition to the time taken to complete the test the number of disks dropped or misplaced was noted. The average time taken to complete the first test was 113.64 seconds; and for the second test 105.43 seconds. There was no obvious increase in the relative time taken to cover the last 4 rounds; the number of dropped or misplaced disks, however, was greater with several subjects, especially towards the end of the test. During the standardization of this test over 100 subjects were tested. The test was severe, and only a limited number could reasonably be carried out on any one subject. Two control tests were recorded on one day—the interval between the tests being 30 minutes—and two "experimental" tests on another day. The interval between the experimental tests was reduced to 15 minutes.

Effect of Multiple Vitamins

Experiments were carried out on 20 subjects, 10 of whom received on three successive days vitamin tablets containing vitamin A 8,000 i.u., vitamin D 1,200 i.u., thiamin 2 mg., riboflavin 4 mg., ascorbic acid 100 mg., and nicotinamide 40 mg. The remaining 10 received tablets indistinguishable from the vitamin tablets. The results of these experiments are recorded below; the mean time (in seconds) is for the complete test. Negative differences indicate that the experimental times are shorter than the control times.

Control Group: Control time, 104.22; experimental time, 104.11
Difference, -0.11
Vitamin Group: Control time, 107.59; experimental time, 104.75
Difference, -2.84

Tests were carried out on two larger groups using vitamin tablets which contained: aneurin 5 mg., riboflavin 5 mg., ascorbic acid 100 mg., and nicotinamide 50 mg. One group received vitamin tablets on four successive days; a control group received tablets indistinguishable from the vitamin

tablets. Tests were carried out on the fifth day. The results of these experiments were as follows:

Control Group (22 subjects):
Control time, 107.43
Experimental time 1, 108.43; difference, +1.00
" " 2, 107.30; " -0.13
Vitamin Group (22 subjects):
Control time, 110.30
Experimental time 1, 109.66; difference -0.64
" " 2, 106.98; " -3.32. Significant

A comparison of the experimental time scores with the control time scores shows that in the control group a diminished score was recorded by 5 in the first experimental test and by 3 in the second; in the vitamin group a diminished score was recorded by 12 subjects in the first test and by 15 in the second test. Co-ordination, as demonstrated by the number of disks dropped or misplaced, was better in the experimental tests in the vitamin group; in the control group there was deterioration in the co-ordination, especially towards the end of the experimental tests. The pulse rate was taken before each test and again within 10 seconds of the end of the test. The interval between the experimental tests being 15 minutes, the pulse rate at the beginning of the second test was therefore a measure of the return of the pulse to normal after the first test. It is noted that the original pulse rates are higher in the majority of these subjects than the generally accepted figure. The drop in pulse rate during 15 minutes is also less than was anticipated.

These experiments were carried out during the spring and summer, and it was noticed that exhaustion appeared to be less marked in subjects who had received vitamin tablets. This observation was not made during later experiments using other vitamins.

Stanmore Experiments

A series of experiments were undertaken using vitamin tablets from which (1) the aneurin was omitted, and (2) both the aneurin and the ascorbic acid were omitted. Personnel from No. 3 Balloon Centre were selected, ranging in age from 18 to 34, and divided into three groups. Group A received tablets containing ascorbic acid 100 mg., riboflavin 5 mg., and nicotinamide 50 mg. Group B received tablets containing riboflavin 5 mg. and nicotinamide 50 mg. Group D received control tablets.

The tablets were given on six successive days, and tests carried out on the seventh day. These men were drawn from various trades, were not volunteers, and were extremely co-operative. The results of these experiments were as follows:

Group A:
Control time, 111.26
Experimental time 1, 109.86; difference, -1.40
" " 2, 107.58; " -3.68. Significant
Group B:
Control time, 115.81
Experimental time 1, 114.93; difference, -0.88
" " 2, 113.23; " -2.58. Significant
Group D:
Control time, 120.98
Experimental time 1, 119.68; difference, -1.30
" " 2, 120.53; " -0.45

A diminution in time scores was therefore recorded after both aneurin and ascorbic acid were omitted from the vitamin tablets. Co-ordination appeared to be better in the vitamin groups than in the control group.

Brighton Experiments

Experiments were carried out at Brighton during October and November on the effect of nicotinamide alone. The subjects were physically fit young men with 6/6 vision selected from U.T. air-crews, and in some cases were volunteers. Control times were recorded on one day, and on the following day each subject was given 50 mg. of nicotinamide at 9 a.m. Tests were carried out at 10.30 a.m. on 23 subjects and at 2.30 p.m. on 16 subjects. The test times of the 23 subjects who were tested 1½ to 2½ hours after receiving nicotinamide were:

Control time, 116.22
Experimental time 1, 111.57; difference, -4.65. Highly significant
" " 2, 111.35; " -4.87. " "

The test times of the 16 subjects who were tested 5½ to 6½ hours after receiving nicotinamide are recorded below and indicate that the effect was considerably less than that recorded above.

Control time, 116.31
Experimental time 1, 115.25; difference, -1.06
" " 2, 114.00; " -2.31. Significant

In November tests were carried out on another group of 19 subjects, all of whom had received 200 mg. of nicotinamide $1\frac{1}{2}$ to 3 hours previously. The test times were:

Control time, 122.26
Experimental time 1, 117.84; difference, -4.42. Significant
" " 2, 115.21; " -7.05. Highly significant

The suggestion was made by Dr. Platt that a single dose of nicotinamide should be given at specified times before the experimental tests, and the experiments were carried out in conjunction with him. It is noted that a somewhat different pattern in the results was obtained.

Having demonstrated that the effect of a single dose of nicotinamide resulted in a well-marked diminution of the time taken to complete the test and that this effect was most marked $1\frac{1}{2}$ to 3 hours after administration of the vitamin, it was essential to ascertain if similar effects would be obtained when tablets were given on six successive days and tests made on the seventh day. This investigation was therefore carried out on 24 I.T.W. subjects at Cambridge in November, and the results were:

Control time, 118.58
Experimental time 1, 116.54; difference, -2.04. Significant
" " 2, 114.62; " -3.96. "

The pattern of these results is somewhat different from that of either of the other groups.

Summary

It has been shown in a series of carefully controlled experiments that the addition of nicotinamide alone, or of nicotinamide and certain other vitamins, to the diet of fit young men results in increased efficiency in carrying out a fairly severe test involving both physical effort and co-ordination.

The test chosen was severe, and called for the utmost co-operation from the subject, whose condition at the end of the test was just short of distress, as evidenced by his breathing and pulse rate.

In earlier experiments the subjects appeared to be less exhausted after the administration of vitamins.

Later experiments appear to indicate that continued heavy or exhausting physical stress may necessitate increasing the dose of nicotinamide.

Experiments which were carried out in conjunction with Dr. Platt and Prof. Ellinger will be reported jointly.

The whole of the work described in this report, and all the projects indicated, have been carried out or planned at the instance and with the support of the Medical Research Council.

I should like to acknowledge my indebtedness to Prof. F. C. Bartlett for his constant help and advice, to Sir Edward Mellanby for his interest and guidance in the administration of the vitamins, and to the many officers of the R.A.F. without whose unflinching help and co-operation this work would not have been possible. I should also like to thank Mr. E. G. Chambers, to whom I am indebted for all the statistical results, and to Sgt. J. M. Yallop (W.A.A.F.) for her assistance in the experiment and for all the clerical work.

ANXIETY STATES IN THE NAVY A CLINICAL SURVEY AND IMPRESSION

BY

G. V. STEPHENSON, M.B., B.Ch.

Surg. Lieut.-Cmdr., R.N.V.R.

AND

KENNETH CAMERON, M.B., M.R.C.P.Ed.

Surg. Lieut.-Cmdr., R.N.V.R.

A survey has been made of approximately 1,300 cases of anxiety state which have been under our care in a Royal Navy hospital during 1940 and 1941. These impressions have been amplified and modified by later experience in the hospital and in a naval depot.

The term "anxiety state" does not reflect the whole picture, but is a convenient designation; the basic condition is considered to be anxiety in its psychosomatic manifestations, and it is this reaction that is regarded as releasing the varied psychopathy of the constitutions affected. Depression in some degree was an almost constant finding in the more established cases, and for descriptive purposes the diagrammatic concept was formed of a straight line with a pure anxiety reaction at one extreme and a depression of the reactive type at the other; clustering around this line there is a big constellation of

symptoms and signs, including hysterical features, any of which may be present or absent. The syndrome may therefore present a very varied picture.

Points of prognostic import in the routine case-history are enumerated, stresses are discussed, the three main phases of development of the anxiety state are outlined, symptomatology as it affects the various systems is reviewed, and a brief summary of methods of treatment is made with a note on the chief elements in prognosis.

Anamnesis

In reviewing the cases an attempt has been made to assess significant factors emerging in the routine anamneses. In the direct family history—i.e., parents and siblings—there is in most cases a sufficient degree of instability to be realized, and quoted by the patient, as "nervous," "worrying," "hysterical." Psychosis is relatively rare. In infancy the more inadequate types produce with monotonous regularity claims that they "were difficult to rear," "have been given up," or "have had pneumonia" an astonishing number of times. By such reflections can one see the image of poor home conditions and an over-worried mother. During school years shyness, timidity, seclusiveness, fondness of reading as recreation or of swimming and walking as sports, all suggest a tendency to withdraw from the demands of schoolboy life and augur difficulty in adjusting later to the very similar claims of the fighting Forces. At the opposite extreme, "the young devil," "always in mischief," and "never out of trouble" indicated by these excesses a temperament often incapable of withstanding the threats and dangers of war.

The standard attained at school was used as a rough preliminary indication of the intelligence level. Truancy in the great majority of cases signified simply marked mental backwardness. Minor degrees of backwardness were by no means of bad import, but if breakdown did occur in such cases prognosis for recovery and return to duty was poor. More valuable, however, was the work record in rapidly assessing a man's prospects in the Service. Frequent changes of job justified in such phrases as "could not stand the heat (noise) in the factory," "had to give it up," "wanted a change," "got fed up," indicate a personality which will adapt poorly to Service conditions. Endless changes of job suggest marked mental defect.

Sexual maladjustment was conspicuously rare as an overt factor in breakdown compared with experience in civilian psychiatric practice. In part this is explained by Service psychiatry's dealing with a much wider group than would in peacetime attend a psychiatric clinic.

Previous organic illness was of importance in focusing anxiety on a system or the basis of hysterical phenomena. Age beyond middle life and arteriosclerosis facilitated the development of symptoms and impaired prognosis.

Stresses

The stresses to which the individual is subjected in the Service are remarkably constant. Separation from home and family bears heavily on the youth, particularly the only or youngest son, for whom the solicitude of the mother is still the criterion of what he may expect from the world: discomforts and hazards are magnified by too sympathetic an appreciation of their importance in her eyes. The older man experiences the rupture of recently established ties or the absence from wife and family, for years an integral part of his daily life. For certain men, to whom the establishment of a home has through the circumstances of their own early lives assumed a peculiar importance, its break-up through conscription and evacuation is often enough to precipitate breakdown. By no means rare; however, were the men in the later thirties for whom war meant a fresh lease of youth and an unacknowledged relief at sloughing, if only temporarily, the burdens and responsibilities of domesticity. For them Nemesis lay in the reaction and behaviour of a wife unreasonably, but with intuitive justice, resentful of the claims of duty.

Particularly difficult situations arise, too, where marriage has been the episode of a short leave and a young wife finds herself still living in the home of his or her parents, with but a wedding-ring to remind her of her altered state and that many barriers

have risen between her and the "good time" she has hitherto enjoyed. The mother, sisters, and men friends of the absent husband are watchfully ready to report and magnify to him her most casual association with a member of the opposite sex. Long watches give ample time for brooding and bitterness, which do much to break down his resistance to more concrete dangers. Similarly does the situation develop of the older man who learns that the mother of his children, to whom war has meant a doubling of her burdens and the withdrawal of support, has sought companionship in a dance hall or public-house, which she has possibly never before entered. The importance of such anxieties goes far beyond the relatively small proportion of cases in which the wife is actually unfaithful.

Physical hardship and discomfort are less obviously a factor in breakdown—the normal capacity for adaptation to them is very great. More important is the effect of lack of privacy and uncongenial company on the white-collar group of the population.

The problem of the "square peg in a round hole" is much more complex than is generally appreciated. During war the Service requires a vast number of men, physically healthy and of average intelligence, who may be trained to be the "working men" of the Service—the seamen, stokers, etc.; it is supplied with civilians accustomed each to his own occupation, trade, or profession. An adaptable individual of the required standard of physique and intelligence is readily trained for the business of war. A man of lesser endowment may have been employed as a civilian in the one sphere where the qualities he possesses are of value, and may have been relatively successful in that sphere. Should this limited type of qualification be one required in the Service, and he be so utilized, he is satisfied. If, however, his experience is not applicable to Service life, or should the number so qualified which the Service requires be small, the man is liable to be employed in a section for which he is not qualified, and his sense of inadequacy is often embittered by the belief that his fate is due to muddling and injustice.

Commonly labelled as "square pegs" are the youths for whom life has yet been too easy, and who are liable to dignify their distaste for continued effort by the belief that they are inappropriately utilized. Finally there are the psychopaths, inappropriate in any section, who too often regard failure in a job of little responsibility as an adequate recommendation for a position of greater trust.

Such maladjustments to the very rigid framework of Service existence are potent causes of anxiety and breakdown.

More intangible factors in maladjustment often present themselves during the period of training—these again more often in the youth who has not yet learned to subordinate himself to the task in hand, and who welcomed his civilian work as a source of livelihood but not his real interest in life. The Service assumes that the individual regards the job as more important than himself. Further, the tradition that only perfection is passable, with the corollary that explanation is no excuse or failure, is still acted on in the Service. These tacit assumptions lie behind much of the tradition of the Service, but to the new entry they may appear as callous disregard for himself as an individual, continual fault-finding, and an unfeeling refusal to listen to reason. In the early stages of training the stimulus and interest of a new life are sufficient to counterbalance these asperities, but in the second or third month, when familiarity has staled but habit has not yet accustomed him to the Service or involved him in the group spirit, the reaction may be one of rebellion, depression, or anxiety. Later, fellowship in responsibility in the smaller units of the ship and growing confidence restore injured self-esteem.

Once at sea the actual physical threats to life present themselves. To the imaginative the period leading up to action often brings the dread of proving inadequate: the inexperienced knows not what to expect; the experienced may dread failing in his responsibilities. The immediate stress, whether from air attack, action, exploding mine, or torpedo, produces a response which may be disability at the time or which by frequent repetition induces disability. Often overlooked are the stresses peculiar to the engine-room branch or stoker ignorant of what is happening above. For him a sudden reverberation, plunging him in darkness and throwing him among clanging and

shifting engine-room fittings, is as much a trauma, whether due to a mine dispatched by his own gear or by a near miss or a bomb or torpedo striking the ship. For the man below deck every possibility lies in the first concussion. At the other extreme lie the experiences of the man too long in northern waters, particularly in small ships. Here monotony of up to a week at sea with a small crew, with short visits to bases that offer no attraction to going ashore, and heavy weather in latitudes that in the winter months mean "darken ship" for 18 or more hours of the day, produce a severe reaction curiously similar to the anxiety-exhaustion and depressive syndrome presented by the sufferer from prolonged or severe stresses by enemy action in more southern latitudes.

Development of Anxiety State and Symptomatology

Subjected to the above-mentioned stresses, the individual tends to react with unexpected uniformity to an eventual state of anxiety which, however varied its manifestations, does in its essentials run true to form. The concept adopted regarding the development of these states was of the psychosomatic unit, subjected to a variety of stresses, endogenous and exogenous, and reacting to these at first physiologically: with undue prolongation of the demands disability supervenes. The less stable types or those in whom there is a smaller constellation of factors making for continued effort break down early; the more stable types and those in whom strong reinforcing sentiments are present do not come under medical care till a more advanced state is reached. The more inadequate types—the temperamentally unstable, the constitutionally inferior, and the mentally backward—often show up in training with mild depressive or hypochondriacal features. They complain of exhaustion, weakness, headaches, or "effort syndrome." (The more robust but maladapted frequently come into conflict with naval discipline at this period.) This may be regarded as the eliminating period of service. The vast majority who survive this test of adaptation may react to conditions of service or stress at sea with disability at three different stages.

Stages of Stress

Immediate stress of danger results at first in what may be regarded as a physiological adrenal-sympathetic response, with a mood of anxious expectancy (Cannon's (1929) "fight or flight" reaction). The physiological propriety of this response is not, however, apparent to the rating, aware only of blurring vision, beating heart, "stomach turning over," and tense or trembling musculature. In the stable, the need for action dissipates the discomforts of his state, and a mood approaching exhilaration often supervenes with gradual relaxation. The temperamentally unstable may over-react, however, to complete ineffectiveness. This may be regarded as disability supervening at the stage of *early stress*.

More commonly the repetition of such dangers leads to a state of heightened expectancy and somatic tension which, while appropriate and in fact synonymous with good morale, may become irreversible when threats are frequent. When relaxation does not occur with relief from strain on leave or ashore, and preoccupation with physical and mental discomforts develops, an anxiety state must be presumed to exist. Presenting himself, the patient may complain of the sense of tenseness or of palpitation, epigastric discomfort, or other correlates of his condition. The clinical picture is of dilated pupils, increased sweating, tachycardia, slight tremor, and increased tendon reflexes. Blood pressure is usually found markedly raised: readings of 170/100 or over are almost routine in the sick bay at this stage. This is regarded as the state of *established tension*.

In most cases of the more stable, conscientious, or experienced types the man may remain at duty for a prolonged period after the stage of established tension. Anxiety and somatic tension, though still present, become less obvious, and the presenting picture is more of depression and exhaustion, with emotional lability and loss of weight. Blood pressure is less elevated, or is even lowered, though tendon reflexes remain exaggerated. It is more commonly in this final state that mis-leading preoccupation with symptoms or signs in relation to one or other of the systems gives rise to the erroneous diagnosis of organic illness. This final state we have termed *anxiety with exhaustion*.

The concept of the development of anxiety state with disability developing at the phase of *early stress*, the state of *established tension*, or final state of *anxiety with exhaustion*, according to the stability of the constitution affected, is clinically valuable from the point of view of prognosis and treatment. In practice, however, the picture present is mixed, and an attempt has been made to discuss the whole range of symptoms. These may be psychic, somatic, or mixed, and vary from mild disturbances of function to gross hysterical features.

Psychic Symptoms

In the psychic sphere the anxiety varies from mild waves in the moments of stress to acute panic attacks. It has been found that even in the sheltered existence in hospital the latter occur, and they are very infectious. Anxiety itself is directed towards a number of different objects. In some, of course, it is the frank fear of danger, freely admitted. It is noteworthy, indeed, in our cases that refusal to admit fears to themselves, with consequential conflict, was very rare, and when it did occur appeared chiefly in the older, better-trained, and obsessional types. In others the object was family responsibility; fear of going insane, of blindness, of something being seriously wrong, especially in those who showed cardiac or gastric symptoms. There was also found the fear of heights, water, and trains, of being shut in or sleeping below at sea. With regard to the family, justification for anxiety often existed when dependent relatives were sick, alone, in poor economic circumstances, or exposed to raids on civilian population.

Sleeplessness was a very common symptom, and presented itself in varying aspects. There was difficulty in going to sleep, or the patient woke up at frequent intervals. Often sleep was disturbed by dreams, and he woke in the morning unrefreshed and with a headache. The dreams also varied. War dreams were common, and the patient often relived some horrifying experience, or woke up sweating after anxiety dreams. Many described their dreams by the phrase "mixed up."

Complaints of being easily tired, of lacking energy, and at the same time of restlessness and being unable to settle are frequently made. Coupled with this was a poor memory for recent events and forgetfulness. Characteristically also there was an inability to concentrate. Some patients found themselves unable to read more than half a page of a book at a time or to take in the gist of the subject-matter.

Loss of confidence and fear of responsibility or of "letting the others down" were both a symptom and a reason for augmented anxiety. Many complained of increased irritability. This appeared not so much with their fellows, since the dislike of company made them desire solitude, as with their home circle. The question, "Does your wife find you more short-tempered than usual?" often brought a rather sheepish reply. "I am afraid so, sir." Emotional disturbance was so constant that it was found advisable to have a small box of gauze squares at hand with which to supply the patient, who frequently broke down and wept during the interview. Increased consumption of alcohol was either an escape from reality or, in some cases, a spur to keep going.

Many of these symptoms explain themselves, and appear either in a setting of anxiety or, not infrequently, without much overt anxiety.

Somatic Symptoms

In the cardiovascular system symptoms were fairly common. Usually the tachycardia and palpitations became the focus of anxiety through ill-advised medical advice in earlier life or variously derived dreads of "heart disease." Precordial pain was often present in such cases and dyspnoea less commonly so. Frequently a man had entered hospital with a diagnosis of cardiovascular disorder based on those symptoms. In such cases no organic lesion was found. It was our experience, however, that the effort syndrome as such was rare in the Navy, and when present emerged generally in the training period and as an anxiety manifestation.

The blood pressure seems to vary at different stages in the illness. In acutely disturbed or shocked cases after some catastrophic event it was found to be low—just above or below 100 mm. systolic. In established cases there was a period when it was raised, while in later cases or those showing exhaustion it was lowered.

In the genito-urinary system frequency of micturition and even enuresis occurred in a number of cases, and may be either a symptom of a fairly severe state or a chronic manifestation without much apparent anxiety. In the former, we consider that both complaints clear up with general improvement but as a chronic manifestation they have proved stubborn and difficult. Experience, however, has taught the necessity for checking a patient's own statements as to how often he micturates. In some cases these have been proved not wholly unconscious exaggerations. Impotence has been complained of in established cases in which the depressive element was strong and is also found to clear up with treatment of the general condition.

Digestive disturbances are frequent. Morning nausea and often vomiting are complained of. Poor appetite is the rule rather than the exception, with the inevitable accompaniment of loss of weight. Functional dyspepsies were not as a rule admitted to a psychiatric ward. They usually are not recognized for what they are, and are admitted for gastric investigation. After negative results have been obtained the neuropsychiatric specialist has been asked to see them. Here, too, it is believed that symptoms are often considerably exaggerated. It is our opinion that gastric investigation should be undertaken in all cases and the psychiatric angle of the case then be tackled. There is usually no difficulty in finding other evidences of the anxiety state; where these did not exist the case was not regarded as psychiatric. Particular importance was attached to impressing medical colleagues with the difference between a dyspepsia in which no evidence of lesion had been shown by a fractional test meal and by radiographs—which remain a medical problem—and dyspepsia occurring as part of an anxiety syndrome.

Other Symptoms

Pain has been met with in every system, and in all parts of the body and all degrees of severity. There is little doubt in our minds that the anxious person is more aware of pain and that his mind, centred on his bodily sensations, has a lowered threshold for pain. A frequent complaint was of "shooting pains all over the body." Various muscular aches in the limbs were common, as was backache. Localization of pain often depended on an associated idea in the patient's mind.

Headaches were almost always present—sometimes accompanied by dizziness and sometimes based on a former head injury. It was often clear, however, that the injury had set the stage for, but was not organically responsible for, this symptom. The headaches, whatever their basis, may appear as a dull ache or a band of tightness, a feeling of vertical pressure, or an acute throbbing sensation in the temporal or occipital regions.

Grosser hysterical phenomena were rare and often occurred on the basis of mental backwardness or in a psychopathic constitution. We attach great importance to the necessity for regarding hysterical manifestations as but symptoms of the fundamental anxiety, and no attempt has been made to separate those cases which showed hysterical phenomena from the general mass of anxiety states. This evaluation of symptom in true perspective avoided the temptation of spectacular "cures" and correspondingly dramatic subsequent conversion phenomena.

While functional weakness of a limb or part of a limb was observed fairly often, paralyses were relatively uncommon, and were certainly on a far smaller scale than was evident in the last war. In many cases the basis was an original organic lesion, and it became axiomatic to seek this organic basis.

Amnesias and fugues occur frequently. In not a few they begin while on leave or on the journey back to duty. Many of these were at a fairly conscious level, and in some cases were judged to be retrospective rather than to be true amnesias. It is considered that they often developed in a setting of mild depression. For a man to claim loss of memory as a reason for evading punishment for being absent over leave is only too easy a way out, from his point of view. A good deal of care was taken to avoid errors in assessing the man's responsibility. Repression and amnesia for painful experience have also been found to occur rarely, and, when present, related to such catastrophic events as being trapped below in a sinking ship; on one occasion they were related to guilty feeling in the patient, who had sought safety while his friend drowned.

Unexpectedly it was found that the conflict between duty and self-preservation was seldom repressed or the basis of a complex-determined symptomatology.

The ordinary man is, in this war, under no difficulty in admitting to himself that he is scared and would prefer to be elsewhere. That he does not give way to this feeling, but rises to the demands of a situation, may be the basis of later anxiety, though not of conversion symptoms. This fact, with the recognition of the anxiety state as such, doubtless explains the relative absence of conversion hysteria.

Anaesthesias and paraesthesias occurred with moderate frequency and varied in degree and situation. Here again there was often an original organic basis. Stammering appeared from time to time, and as a rule there was a similar history of this trouble in childhood.

Minor disturbances of vision were relatively common, although the grosser ones were less often seen than might have been expected—e.g., photophobia, occurring after exposure to explosion flash. Far more frequent were blurring of vision, with "spots before the eyes" and amblyopia. Night blindness was a common complaint, and in not a few instances functional failure to focus. This was chiefly demonstrated in those with a refractive error which was not improved by appropriate lenses. Visual complaints failing to improve with the general condition were in a significant number of cases found to be based on blindness in a relative and a corresponding fear in the patient.

Only a few cases of aphonia were seen; these usually clear up rapidly.

A history of "collapses," fits, and faints was commonplace, but occurrence of such in hospital was on the whole rare. They were not always easy to assess, for the classical hysterical fit was seldom seen. Some were undoubtedly syncopal attacks, others vasovagal, but there was a considerable group that did not fall into these categories, nor were they epileptic.

Treatment

Most cases seen in hospital are those which treatment from the ship's medical officer or in the local sick bay has failed to clear up. Briefly, such treatment has consisted of encouragement, reassurance, and sedation with short periods of rest in the sick bay. It must be emphasized that a large proportion of the milder anxiety states are adequately treated in this way and never reach hospital—treated often by medical officers who themselves experience corresponding stresses and are well able to judge the severity of the symptoms. The treatment to be discussed, however, is that of the cases that enter hospital.

Here the basic principle adopted has been that of resting over-stimulated organism as a first measure and bringing back to normal functioning as the second. Admission to hospital secures relief from the immediate situation; rest in bed, with the use of normal sedatives—i.e., bromides by day and barbiturates by night—and recourse to paraldehyde for the restless, is sufficient to ensure relaxation in the milder cases. Where loss of weight, debility, and exhaustion occurred without marked tension an effort was made to build up the physical condition and bring about an increase in weight. The usual methods were adopted, but a useful adjunct was the administration of insulin and glucose daily over a period. Small doses of from 5 to 10 units twice daily were employed with liberal carbohydrates. We did not use insulin sapor.

In cases in which exhaustion and loss of weight are marked and emotional tension is so severe as to prevent relaxation continuous narcosis has been found of great value. It has also been highly beneficial in cases admitted immediately after heavy raids or attacks, when the patient may show violent agitation, gross tremor, and somatic disturbance so pronounced as to render him inarticulate or even to produce a confusional element. The technique is a modification of that described by Mira (1939). For hyoscine, which frequently proved toxic, paraldehyde has been substituted. The treatment lasts for 72 hours; sleep is maintained by 1½ gr. of phenobarbitone 4-hourly during the whole period. This is reinforced by 2 drachms of paraldehyde, administered freely up to 10 to 12 drachms in the 24 hours. Ordinary light diet is given, with fluids "pushed."

Used as an immediate treatment in grossly agitated and acute cases this technique has proved spectacular in relieving

the patient's distress and subduing the gross physical disturbances that are otherwise apt to be hysterically prolonged. All cases, however, so treated have shown marked improvement in physical condition. Emotionally there is a sense of relaxation, sleep is re-established, tremors disappear, and the patient is encouraged by the feeling of relief and relative well-being. The improvement, however, is regarded as but a first step most significant in men of good personality whose symptoms have been precipitated by prolonged or severe stress of active service. In the more inadequate and unstable types, whose anxiety is a reaction rather to the situation of war than to specific stress, the disturbing factors tend to come into play again as soon as full consciousness is regained. Cases showing depressive factors also react well.

Psychotherapy, as such, was of necessity superficial and symptomatic or limited in its application to problems of adjustment to Service life or conscious experiences. While an essential part of the treatment of every case, it is probable that by itself it seldom made the difference between a man's retention or discharge from the Service. In minor hysterical phenomena, such as tremor or spasm, treatment was firmly directed towards the underlying anxiety state, and, in the main, symptoms liable to be prolonged were found to clear up *passu* with the general condition. Suggestion and persuasion were occasionally of value as symptomatic treatment. A certain amount of relief is obtained with abreaction, and recovery from painful experiences with direct hypnosis or by the medium of narco-analysis as described by Mallinson (1940). Again, however, the general condition remained to be treated.

Occupational therapy, physical training, gardening, and hospital concerts were useful measures in returning to normal attitudes. The patients, too, were encouraged to go for afternoon walks outside the hospital grounds when possible.

The adjustment of concrete personal and domestic problems where possible, was regarded as of such importance in promoting recovery that particular attention was paid to it. Too much stress cannot be laid on this. The recognition by the executive authorities of recommendations made was helpful, while the Welfare Officer and the Royal Naval Benevolent Trust invariably assisted when approached.

The prognosis of every case was assessed as soon as possible after admission and the patient informed. Those in which the outlook was thought to be unfavourable were recommended for consideration for invaliding as soon as they were well enough to be discharged to civilian life.

Hospital treatment beyond two to six weeks was required only in a small proportion of cases, and, in those, transfer to an establishment devoted to rehabilitation measures was effected. A moderate period of sick leave gave the stimulus of restoring personal relations, relieved domestic anxieties, and revived sense of independence; but prolonged leave was recommended with increasing discretion. The men returned to full duty, frequently to service on shore preliminary to full service. While on shore service they were recommended to be under the eye of the neuropsychiatric specialist in their depot. He could then give the appropriate guidance to the executive authorities to maintain contact, and arrange for suitable employment in depot or finally effect return to full duties at sea in an area of diminished stress.

Prognosis

In general it was found that the results of treatment were satisfactory. Prognosis was poorer in the cases described as constitutionally inferior or temperamentally unstable, particularly when allied with any degree of mental backwardness. It was also poorer where a prolonged state of tension had preceded a severe trauma such as being trapped in a sinking vessel. No close relation between age and prognosis was observed, except where the factor of arteriosclerosis entered. In such cases prognosis was bad.

The general result of our observations has been that there is a remarkable capacity for recovery from anxiety states in the averagely endowed and stable individual. Except where the above-mentioned factors operate, return to duty at sea with repeated stress can be anticipated.

Even in the cases of poorer prognosis return to some form of service in a position of diminished stress can be achieved in a large proportion of cases. Particularly has this been found

to be the case since a neuropsychiatrist has been established in the depot, with all his advantages in familiarity with conditions and demands and power to recommend disposal.

We wish to express our thanks to Sick Berth Petty Officers Orr and Winsor for great pains in extracting the case material and copying the drafts on which this article is based.

NITROUS OXIDE ANAESTHESIA: A CRITICAL EVALUATION.

BY

R. BLAIR GOULD, M.B., Ch.B., D.A.

Anaesthetic Specialist in the E.M.S.

Nitrous oxide-oxygen is usually considered the safest and best anaesthetic agent. At the present time, when non-experts in increasing numbers are being called on to act as anaesthetists in both military and civil practice, a critical examination of this statement is necessary.

While quite suitable for many operations on susceptible patients, nitrous oxide, being the weakest of all anaesthetic drugs, is rather an agent for the production of unconsciousness than one which can provide any degree of muscular relaxation. The attempt to produce the former in many anaesthetic-resistant patients and the production of the latter in nearly all cases are usually accompanied by such a degree of anoxia as may often be dangerous. Thus Macintosh (1938) states that "its use by inexperienced anaesthetists for major surgery is fraught with disappointment if not carried out boldly, and with danger if it is"; while Clement (1939) in the standard work on the subject acknowledges that "deep, prolonged anaesthesia with nitrous oxide implies a drastic and continued curtailment of the oxygen supply which greatly augments any degree of anoxaemia that may be present" (p. 97); and, again, "The abnormalities" (of respiration) "occurring in the deeper planes are all evidences of oxygen want. . . . The symptoms produced in the nervous system by nitrous oxide-oxygen administration are in reality those of a gradually progressing state of anoxaemia" (p. 40).

Arguments against Nitrous Oxide

In these circumstances, why is nitrous oxide anaesthesia continually recommended when its use must often imply considerable oxygen want? The three main arguments are all propounded by Clement: (1) that anaesthetic agents in general produce their effects by reduced oxygen utilization, and nitrous oxide in particular "by the exclusion of the oxygen in the inspired air" (p. 98); (2) that nitrous oxide is an indifferent inert gas without any direct action or effect upon the body tissues (p. 23), and it is assumed, therefore, that any additional effect of anoxia on the tissues will be minimal, if not harmless; (3) that "the body shows a remarkable tolerance to moderate, and even temporary severe, degrees of oxygen want" (p. 97). In my opinion the weight of evidence is against each of these statements.

1. The theory that the narcotic action of anaesthetic drugs in general, or of nitrous oxide in particular, is due to depressed oxygen utilization is not supported by recent research. Henderson (1930), after reviewing considerable evidence, concludes that "oxidative processes and narcosis are separate phenomena. . . . No theory of anaesthesia will prove acceptable which is based on a proof of a depression of the resting oxidation of the cell." Pask (1941) reviews the recent work on this subject, and also concludes that under clinical and experimental conditions anaesthesia has no effect on the oxygen uptake of the intact organism or of isolated tissues.

2. Nor can it be assumed with certainty that the effect of nitrous oxide on the tissues is negligible. Clinical experience does not support this assumption, for short anaesthetics for minor surgery, even in the absence of anoxia, are often followed by headache, vomiting, and a feeling of distress and giddiness. Macintosh and Bannister (1941) state that they attempted to produce anaesthesia sufficient for dental extractions in 50 cases by nasal administration of nitrogen, and "although in all cases unconsciousness was reached, in the robust or anaesthetic-resistant type the full anaesthetic state

was not achieved. . . . If nitrous oxide has no anaesthetic effects, but acts only as an oxygen replacer, any inert gas would furnish as satisfactory an anaesthesia; actually, the anaesthetic properties of nitrogen are not as effective." Even were this assumption to be true, it is difficult to understand how it would render less harmful the effects of frank anoxia on tissue cells. Experience shows that the adoption of this assumption as a working basis often results in an anaesthetic technique which cannot be considered good practice.

3. The statement of Haldane (1922) that "anoxaemia not only stops the machinery but wrecks the machine" would appear to me to be as applicable to anaesthesia with nitrous oxide as to any other clinical condition. Indeed, recent research and clinical experience have not only confirmed Haldane's work but have demonstrated that the effects of anoxaemia may be insidious or delayed (Armstrong, 1939). Thus Samson Wright (1940) concludes: "A slight degree of oxygen lack may therefore act insidiously and only reveal its effects after a long latent period. . . . Following prolonged severe exposure to oxygen lack, very formidable after-effects occur." Courville (1936, 1939) has produced convincing evidence of the damaging effect which oxygen deficiency during anaesthesia, especially with nitrous oxide, may produce on the central nervous system, particularly on the cortex. He has shown how minor degrees of anoxaemia may cause permanent damage, which may not become apparent until after a considerable latent interval, while even a few minutes of severe anoxaemia may produce permanent damage. As Pask (1941) has emphasized, "immediate apparent recovery from a period of anoxia does not necessarily mean that a patient, particularly a shocked patient, has not suffered harm."

Cyanosis

Clinical experience does not support the view put forward by Clement: "The difference between the cyanosis associated with nitrous oxide-oxygen and that with other anaesthetic agents has been frequently overlooked" (p. 38); "cyanosis, during nitrous oxide-oxygen anaesthesia has been given the same significance as with all other anaesthetics, thus the mode of action of nitrous oxide in producing anaesthesia by the exclusion of oxygen is ignored" (p. 103). The implication in these statements is that cyanosis is of a different nature when associated with nitrous oxide, and they have often been taken to justify its use in circumstances which must imply a considerable degree of anoxaemia.

Cyanosis depends on the absolute amount of reduced haemoglobin in the blood, the amount of oxygenated haemoglobin present being of little importance (Lundsgaard and van Slyke, 1923). Thus in plethoric individuals cyanosis may occur without anoxaemia, but such patients form a very small proportion of those coming to operation. Unless the haemoglobin concentration of any surgical patient is known to be above normal the possibility of cyanosis occurring without anoxaemia may be ignored.

Far different is the case with anaemic patients, who, in surgery, comprise the great majority. Here, the oxygen-carrying capacity of the blood being below normal, even when fully oxygenated there may be some anoxaemia, although the amounts of reduced haemoglobin present in the capillaries may not be sufficient to produce clinical cyanosis. But when the latter is present, the amount of haemoglobin available for carrying oxygen is further reduced and oxygen want intensified. Cyanosis therefore must be prevented in anaemic patients if anoxia is to be avoided.

McCarthy (1941) has described signs, affecting the respiratory and circulatory systems, by which he considers anoxia may be recognized, irrespective of the presence or not of cyanosis. Unfortunately, however, in my experience these signs do not occur in minor degrees of anoxaemia, where their value would be greatest; they are almost invariably late signs, indicating that circulatory and respiratory depression is already profound.

Prevention of Anoxaemia

It would appear, therefore, that the only method of avoiding anoxaemia is by maintaining scarlet blood in all cases. Where, however, anaemia is known to be present before operation, or is produced during operation by blood loss or other means, then not only must cyanosis be prevented but an increased concentration of oxygen must be given, over and above that necessary to produce scarlet blood, to compensate for the reduced haemoglobin, for by this means an increased blood-oxygen concentration may be produced (Boothby *et al.*, 1939, 1940; Wood, Mason, and Blalock, 1940).

Clement, however, states that "it is impossible to produce narcosis (with this agent) in the majority of patients and still maintain a pink skin and scarlet blood" (p. 103). This conclusion has a profound bearing on the evaluation of nitrous oxide as an anaesthetic agent, for I would regard the maintenance of a pink skin and scarlet blood as essential in all cases. The prevention of anoxaemia is one of the primary duties of the anaesthetist, and I would submit that to avoid anoxaemia nitrous oxide must be used with great discretion, particularly in shocked or anaemic cases. "Agents are potent or impotent as their toxicity is great or small" (Gillespie, 1942). To increase the potency of a weak agent such as nitrous oxide by associating with it any degree of tissue anoxia, however mild, is in my opinion to employ a method whose toxicity to those tissues may well be lethal; for there is much evidence that, whereas the effects of anaesthetic agents on tissue cells (in the absence of anoxia) are recoverable, the effects produced by anoxia are irreversible. (While I consider abundant oxygen essential with any anaesthetic technique or drug, I doubt whether the advantages of nitrous oxide are great enough to justify the additional transport of the necessary nitrous oxide cylinders to all the various isolated theatres of war.)

Other methods of increasing the potency of nitrous oxide are available, and are to be preferred. I do not agree with Clement that by the addition of ether, for example, to the mixture "the benefits of gas-oxygen alone are largely sacrificed" (p. 103). I would rather submit the principle advanced by Lundy (1932)—of the use of a combination of agents or methods to decrease the toxicity of a single agent—as being a more rational principle on which to base anaesthetic practice. In my opinion, the addition of some supplementary agent to nitrous oxide anaesthesia confers a benefit to the patient in that it enables the anaesthetist to maintain anaesthesia in an atmosphere of abundant oxygen.

Summary of Conclusions

Nitrous oxide is a weak anaesthetic agent whose effects are often produced only in the presence of anoxia.

The recognition of anoxia being difficult or impossible in many cases, it is better to avoid it by increasing the oxygen content of the anaesthetic mixture.

Should this render anaesthesia with nitrous oxide difficult in any particular case, it is an advantage to the patient to add some supplementary agent, for reduction in the oxygen supply to "potentiate" nitrous oxide is never justifiable.

It follows that nitrous oxide anaesthesia is not as safe as often supposed, and its application should be strictly limited.

An important factor in the first phase of injury from cold, states Killian (*Zbl. Chir.*, 1943, No. 2), is the production of heat by contraction and tremors of the muscles. In the resynthesis of the lactic acid thereby formed, an important part is played by the phosphorylation which is controlled by the suprarenal hormones. If the suprarenal hormones are lacking, severe disturbances of muscular metabolism and cardiac metabolism must ensue. Exposure to cold for long periods results in the supplies of cortical hormones being used on account of muscular exhaustion. Since cortical insufficiency enters into the picture of shock and collapse, casualties showing these signs are specially liable to damage from cold. In the second phase of frostbite, where oxygen lack in the tissues is the dominant feature, there is not only an abnormal consumption of "cortin" but an actual lesion of the suprarenals. Cortin, Killian believes, seems to be justified in cases of extensive frostbite, especially those showing toxic symptoms.

MARCH FRACTURE OF THE METATARSAL BONES

BY

H. H. FOURACRE BARNES, M.B., B.S.,
F.R.C.S., M.R.C.O.G.

Flight Lieutenant, R.A.F.V.R.

March fracture, or spontaneous stress fracture, is most often seen in the metatarsal bones, but has been observed in others, including the femur (Peterson, 1942). This type of fracture was well recognized before and during the war of 1914-18. A number of articles have been published recording cases that have appeared during the present conflict.

A Series of Cases during Training

This communication records 20 cases of march fracture of the metatarsal bones that have occurred during the first five months of the training programme at a recruits' training station in the Royal Air Force. The training programme is in two parts. The first part, of three weeks' duration, is devoted mainly to disciplinary training; the second part, of five weeks' covers more advanced subjects, including those which are more strenuous, such as bayonet-fighting, unarmed combat, etc.

The number of recruits passing through the station during the period in which the fractures occurred was seven thousand, so that the incidence is small. With three exceptions the patients were from 18 to 21 years of age. This cannot be taken as significant, however, as the age of the majority of the trainees falls within this age group. All the patients were of the highest medical grade (Grade 1) on entering the Service, and their physique was classed as normal in half the cases and medium in the remainder. No obvious foot deformity was observed in the patients. Their histories revealed that the majority, previous to entry into the Service, lacked regular exercise and were in occupations necessitating long hours of standing. Eight of the 20 had been in the A.T.C., in which they did drill from one to three times a week for periods ranging from three months to two years. All the fractures occurred during the last five weeks of training.

The injuries were sustained during active exercise and were due to indirect trauma. One patient, however, sustained his fracture during a fall at football. His legs were tangled up with those of another player. This is the only case in which direct trauma may have been responsible. Of these 20 fractures 10 developed during route marches, 2 while bayonet-charging, 2 at drill, and another at football as already mentioned; the remaining 5 could not be ascribed to any particular exercise.

It is usually stated that the onset of symptoms is insidious (Drummond, 1940; Krause, 1942). This was not the common finding in the present series. In 2 of the earlier cases the histories are incomplete, but of the remaining 18 the onset of symptoms was sudden in 12 and insidious in 6.

Pain, localized to the affected bone, is the chief symptom. This is felt on standing, and especially when on the toes. This causes the patient to limp and, when the second or third metatarsal bone is affected, to walk on the outer side of the foot. A sensation of stiffness of the toes is often experienced. This is presumably due to reflex spasm of the interosseous muscles. A few hours after the onset of pain some swelling which pits on pressure, may be observed on the dorsum of the foot at the base of the toes. There is localized tenderness but bruising has not been noticed in the present series. The right foot was affected in 10 patients and the left in 10 also. There were 15 fractures of the third metatarsal, 3 of the second and 2 of the fourth. In the large series of cases analysed by Tobold (1903) and Jansen (1926) the fracture was found to occur more frequently in the second metatarsal bone.

Radiography in Diagnosis

In order to confirm the diagnosis of the early case first-class x-ray pictures are needed. In the present series two views of the foot were taken—an antero-posterior with the foot in the normal standing position, and another antero-posterior with the foot in the everted position, thus taking an oblique view of the foot. In a number of cases no fracture was to be seen in the antero-posterior view but could be seen in the oblique view. This is due to the fact that the earliest signs of fracture

of the metatarsal, which consist of a fine periosteal reaction with or without a small crack in the cortex of the bone, appear on the dorso-medial aspect. In 16 of the 20 fractures these early signs could be seen. Of the remaining 4, one was a comminuted fracture, another an impacted fracture, the third an oblique fracture of the shaft, and the fourth was not confirmed by x-rays until five weeks after the onset, the early radiographs showing no fracture. Eleven of the fractures were at the middle of the shaft, 7 were about a quarter of an inch from the neck, 1 was at the neck and impacted, and 1 was an inch from the base of the bone. With the exception of the comminuted fracture and the oblique fracture, there was no displacement of the fragments of bone. The absence of shortening and angulation suggests that the force responsible for the fracture is not great enough to produce separation of the fragments to any appreciable extent and that the surrounding tissues are themselves little damaged and tend to hold the fragments in position.

The first radiograph, taken immediately after the onset of symptoms, may not show the early evidence of fracture, whereas the fracture may be seen in a second radiograph taken some 7 to 10 days later. In 3 patients of the present series this state of affairs existed. Between the first and second radiographs the only treatment given was strapping and light duty, the plaster method being used when the diagnosis was confirmed by the second radiograph. In a fourth patient the first x-ray film showed no fracture, but in spite of this plaster treatment was given for four weeks, and then a film was taken for the second time. This showed the fracture and the formation of callus.

Treatment

The treatment in the present series has consisted of a below-knee plaster, with a walking-heel attached, for approximately four weeks. The toes have been left free on the dorsal aspect and the ankle has been immobilized at a right-angle. Following this the patient has had two weeks' light duty, avoiding all vigorous exercise. At the end of the six weeks he has resumed full duty with the exception of excessive exercise and long marching. No residual disability has been encountered.

Discussion

The aetiology of the lesion is obscure. Jansen (1926) suggested that a reduction in the nutrition, caused by swelling of the interosseous muscles, made the metatarsal bones brittle. It has been suggested by Wilhelm (1941) that vitamin deficiency may play a part, but there is no definite evidence to support this. Moore and Bracher (1941) have drawn attention to the possibility of exercise other than marching being responsible. Krause (1942) believes that the mechanism is rhythmically repeated subthreshold mechanical insults acting by summation to a point beyond the capacity of the bone. It is now well recognized that the fracture tends to occur in recruits who have led inactive lives before entry into the Service. This must therefore be accepted as the predisposing cause. In addition, as the name implies, the fracture usually is a result of marching, and some such form of exercise would appear to be the exciting cause.

The striking feature in the present series—a feature to which little attention has been drawn in the past—is the situation of the early signs of the fracture, in the x-ray film, on the dorso-medial aspect of the shaft of the bone. Inspection of x-ray photographs in articles on the subject also shows this situation of the early signs. This suggests that the exciting force acts in such a manner as to bend the bone in an outward and downward direction and so produce a tear of the periosteum and a crack in the cortex of the bone, first on the dorso-medial aspect.

The injury to the periosteum causes a reaction, which shows in the radiograph as a fine opacity by the shaft of the bone. This reaction and the actual break in the cortex may not be visible at this early stage. Later the periosteal reaction has increased and the interval between the fragments may be more definite as a result of some absorption of bone at the ends of the fragments at this point. This sequence of events offers an explanation for the apparent absence of the fracture in the first radiograph and its subsequent appearance in a second radiograph some days later. The periosteal action continues, so that after four weeks a spindle of callus may be observed around the shaft of the bone, centred about the fracture line,

which may now be seen involving the whole width of the shaft. It is at this stage that the lesion may simulate a sarcoma in the film, and a definite hard swelling may be felt on the metatarsal bone. The swelling is not tender and there is usually no disability.

It is possible that the force which tends to bend the bone in an outward and downward direction results from muscular action. This force is probably brought into play during the action of marching when the weight is being transferred from one foot to the other. The affected foot is then in the dorsiflexed position and the plantar flexors of the toes and foot are contracting to give the springy movement as the weight is being transferred from that foot to the other. As Krause suggests, repeated strain on the shaft of the metatarsal may finally result in the fracture.

A reduction in the incidence of the lesion seems probable if, first, the training of boys before entry into the Service in such youth organizations as the A.T.C. is intensified with regard to the physical development; and, secondly, the training programme for the recruit is modified so as to reduce the amount of marching in the first two months of training. The marching programme should be carefully graduated, especially when other vigorous subjects are included in the syllabus.

Summary

Twenty cases of march fracture of the metatarsal bone in recruits are recorded and analysed.

The clinical findings are described and the x-ray appearances discussed.

It is suggested that the exciting force responsible for the fracture is supplied by the repeated muscular action of the plantar flexors of the toes and foot during the springy movement of walking.

Suggestions for the reduction of the incidence of this type of fracture are offered.

I wish to express my gratitude to Air Marshal H. E. Whittingham for permission to publish this article; to Wing Commander W. G. S. Roberts for facilities for investigating the cases; to Squadron Leaders R. J. Coto and C. Wilson for allowing me the opportunity of seeing the cases; and to Sgt. F. E. A. Blackman, M.R.S., and Mr. F. Newman for their excellent x-ray work.

Medical Memoranda

Cardiac Failure treated by Mercurial Diuretics over a Prolonged Period

The following case may be considered interesting enough to warrant publication.

On Dec. 12, 1930, a farmer's wife aged 55 was visited on account of morning occipital headaches, giddiness on stooping, and dyspnoea on exertion, all of insidious onset over the past year. She weighed over 15 st., and had a large post-operative ventral hernia, since repaired under spinal anaesthesia. Her lips were mildly cyanosed. There was no oedema of the extremities. Her arteries were not unduly thickened and her pulse was regular in rhythm, of increased force, large volume, and high tension, while the rate was 92 a minute. Her blood pressure was 220/130 mm. Hg. Examination of the heart showed a forcible but localized apex beat in the sixth interspace outside the mid-clavicular line. Being so obese, accurate percussion of the cardiac dullness was impossible. A conducted ventriculo-systolic murmur was most audible at the apex, due to relative mitral incompetence. A moderate degree of basal bronchitis was present. The urine contained less than 0.025% of albumin, and no casts or red blood cells were present in repeated specimens. Her previous history was negative except for puerperal fever after one of her confinements 30 years earlier.

Her case was considered to be one of essential hypertension with insidious onset of cardiac failure. Reduction of weight, a salt-free diet with salt substitute, rest, and iodides were prescribed. She improved, and continued to be moderately well until Feb. 13, 1933, when I was called to her on account of intense orthopnoea. She was suffering from auricular fibrillation—the pulse rate being 138 a minute. Massive digitalis therapy was instituted, 4 drachms being given then and a further 2 drachms on the following day. After two more days digitaline Nativelle (dipoxin B.P.) granules gr. 1/600 were given thrice daily, until on Feb. 22 the pulse rate had fallen to 69. It has since been maintained over the past 10 years between

65 and 85 when at rest by giving 5 to 6 granules a week and by watching carefully for signs of over- or under-dosage.

She remained well and was able to continue with her household and dairy duties until dropsy of cardiac type intervened in Feb., 1936. This was cleared by means of rest in bed, salt-free diet, and diuretin gr. 15 thrice daily, but it returned quickly in spite of perseverance with the treatment. It was, however, delayed in its severity until the end of May, when she was so badly swollen and so miserable as to necessitate her being kept sitting up in bed resting forward on her thighs. The oedema was extreme, and the end would appear to be not long delayed. Opiates were given for her relief, and had to be administered by mouth as she lived seven miles away. On May 30 I gave her 20 gr. of ammonium chloride to take in a mixture thrice daily, and on June 3 she received 1 c.cm. of salyrgan intramuscularly into the buttock. The diuresis was moderately profuse. On alternate days 1 c.cm. was continued, and with caution, for two more doses. On the fourth occasion 2 c.cm. was given—the ammonium chloride being also given, as before.

By June 24 she had received salyrgan thrice weekly in 2-c.cm. doses and the oedema had disappeared. The urinary output was examined, and always has been, at each visit. I found it necessary to continue thrice-weekly injection until Dec. 2. By that time it was considered necessary to give it only twice weekly. She had been allowed up gradually in August, until she was able to do her housework over eight hours daily, and has continued to do this ever since. From Dec. 5, 1936, to July 27, 1942, 2 c.cm. of salyrgan or mersalyl (B.D.H.) was given twice weekly with few exceptions.

The patient at this date decided to "retire" from active work and live more leisurely. Since then 2 c.cm. given weekly, and with occasional extra doses, has kept her oedema-free, except for a slight puffiness of the feet and lower legs. Altogether she has now had 680 injections—all but a very few being of 2 c.cm.

COMMENT

The only toxic symptoms that might be ascribed to mercury have been: (1) A "soapy" feeling in the mouth. This is almost constant, but there has never been any sign of stomatitis. The patient wears dentures, and so oral sepsis has not been present to help induce the condition. (2) Three slight attacks of catarrhal colitis have occurred, each lasting two to four days and each signified by griping pains on the left side of the abdomen and by tenesmus, with the passage of mucus usually tinged with blood. These attacks responded quickly to withdrawal of the diuretic for a week and the administration of 10 gr. of Dover's powder thrice daily for a few days along with a roughage-free diet.

There have been no signs of neuritis—her deep reflexes being maintained, in addition to there being complete absence of paraesthesia and tremor or of any mental disturbance or drowsiness. She has had frequent severe cramps in her legs about 48 hours after an injection. These were most marked when she was on a salt-free diet. When returned to a normal salt-containing diet these attacks became infrequent, and since receiving her injection once weekly have been altogether absent. It was noticed that it was wiser to allow a slight pitting of the ankles to remain at all times to prevent too much dehydration. These cramps are of the nature of stoker's cramp. The kidneys have shown no evidences of increased impairment over these years. The amount of albuminuria from passive congestion seldom exceeds 0.1%, and only an occasional hyaline or granular cast is found. Haematuria has been absent. Nausea has been complained of from time to time, but is usually attributable to the ammonium chloride, which, however, is required in this case as the diuresis is about halved without it. On rare occasions the nausea has been due to the onset of digitalis sickness.

It is interesting to note that the patient has at no time suffered from any signs of thrombosis—either arterial or venous. Of course her arteries are ideal, being free from obvious arteriosclerotic changes and probably from atheroma. Also no local reactions have occurred.

CONCLUSIONS

It would appear that there is little risk of any untoward symptoms of mercurialism arising from the prolonged administration of salyrgan or mersalyl (B.D.H.) even when given at such short intervals in cardiac dropsy, provided that elimination is not impaired by renal disease and that oral sepsis is not present.

There would seem to be no danger, or little danger, of thrombosis occurring provided that the blood vessels are reasonably healthy.

Cramps may be avoided after injection by giving sufficient salt in the diet and by avoidance of over-dehydration.

No local reactions should occur if injection is given deeply and with a dry needle.

It is worth while to institute treatment even when the patient is apparently in *extremis*, as many years of moderately active life may be enjoyed.

Reviews

A TEXTBOOK OF MIDWIFERY

Textbook of Midwifery. By Wilfred Shaw, M.D., F.R.C.S., F.R.C. (Pp. 588; illustrated. 21s.) London: J. and A. Churchill. 1943.

It is perhaps natural that students should encourage a poor teacher to write a textbook on the subject he teaches. certainly a good thing that not all such encouragement fruit in the shape of new textbooks on this and that, for each has a real contribution to make it has no valid excuse its existence. There is nothing revolutionary in Mr. W. Shaw's new work and little to distinguish it from other books on midwifery, but none the less it is assured of a warm welcome, for its earlier and sister volume on gynaecology given the author a well-earned reputation as a teacher extends far beyond the bounds of St. Bartholomew's at students.

Mr. Shaw's obstetrical teaching is based on three principles. The first is that the majority of women do themselves spontaneously without much trouble; the second that great clinical judgment is required to decide if and interference is indicated; the third is that if any obstetrical manipulation is carried out it calls for dexterity and operative skill of a very high order. As would be imagined from the practice of midwifery has been described largely from a practical and clinical basis. The book is introduced by a chapter which the author states is intended to illustrate attitude to the practice of midwifery. It is a creed based on genes, meiosis, and the blastopore, and the student may to read it more than once before he understands its meaning. If he does need to do so he will not be the loser, because he will begin his studies with the oft-repeated assurance from his mind that unnecessary interference is the greatest obstetrical practice.

The book is arranged on conventional lines. There are sections dealing with physiology of reproduction, clinical midwifery, complications of pregnancy, abnormal labour, malities of the amnion, placenta, umbilical cord and management and diseases of the newborn, operative midwifery and results and statistics. Excellent illustrations are distributed throughout. A minor criticism is that here and there the author is left wondering what Mr. Shaw believes and practises. In this practice is made clear it is of little help to the student. He is told that some authorities advise episiotomy in all deliveries or that many obstetricians have no anxiety in forming a Caesarean section after a surgical induction of labour by means of the Drew-Smythe catheter, to quote only a few examples. Dogmatic teaching is often dangerous, but it is so in clinical medicine than are the vague utterances of an academic tutor. The student must learn how he is to tackle clinical problems when they arrive, and he can measure the value of his teacher's dogma by the results he achieves.

Considerable emphasis is given to radiological examination of the pelvis—even, some would think, at the expense of instruction on when and how to examine a pelvis clinically. It is admitted that "there is much to be said for the fashioned vaginal examination by an experienced obstetrician and it is also admitted that perhaps radiological methods lead to unnecessary interference. On the other hand the student is informed that radiography is the only scientific method of pelvic measurement without being reminded that obstetrics is an art and not a science. He is taught that a floating head is always an indication of disproportion and one finds it difficult to reconcile this with either the principles so clearly defined in the introduction. The student believes that the high head always indicates disproportion and that the only scientific means of investigating the pelvis is by radiography, then the stage is set for interference and plenty of it. The discussion on the treatment of degrees of disproportion includes an excellent account of the degrees of labour. Many of Wilfred Shaw's colleagues will disagree with his views on the methods of terminating pregnancy. He advises abdominal hysterotomy from the 12th to 18th week, vaginal manipulation from the 18th to 28th week, while the uterus is notoriously inert, is strange indeed. A sur-

mission is the lack of reference to the importance of the Rh factor in obstetrics.

Major place in this review has been given to criticisms which or the most part are levelled against details in the text. We venture to prophesy that the next edition of this book will be considerably revised and correspondingly improved.

AUTHORITY IN MEDICINE

Authority in Medicine: Old and New. By Major Greenwood, D.Sc., F.R.C.P., F.R.S. The Linacre Lecture, May 6, 1943. (Pp. 32. 1s. 6d.) Cambridge: The University Press, 1943.

Though Linacre's name is venerated his memory is but hazy. Nevertheless when Prof. Topley said of him in the Linacre Lecture for 1940 that "the only reason he did not do more harm than he did was because the times were too much for him" the audience were mildly shocked; the offence in Prof. Topley's eyes being that Linacre's object was to diffuse accurate knowledge of the ancient treatises, especially of Galen, which would merely put "a brighter polish on the fetters that old medicine in thrall"; in other words, an authoritarian wished to impose a still older authority on us. Prof. Major Greenwood in his Linacre Lecture for 1943, on "Authority in Medicine: Old and New," questions the justice of this criticism, and starts by going back to Galen himself, who was "almost comically unlike one's idea of an oracle or a prophet," though, like the Hebrew prophets, he had "an extremely low opinion of most of his contemporaries and an immense command of the vocabulary of vituperation . . . he was for ever giving reasons, he was sometimes witty, often abusive, but always arguing." His views on hygiene were sound, his medical psychology was in advance of his age. There was in Linacre's day "a Galenical faith, just as there is now a Marxian faith, and medical students at the end of the fifteenth century were no more familiar with the works of Galen than young English sectaries of Marx with his opinions; probably less." It is not Galen who should be blamed, but the misuse made of his writings in an age when, largely due to ecclesiastical influence, the spirit of authority was supreme. It is the fate of great teachers to start as revolutionaries and to become the idol of reactionaries.

Authority there must be; the medical curriculum, lengthy as it is, would be inordinately prolonged "if every student verified experimentally textbook statements." With us a special authority attaches to the experimental method, but we may overrate its logical value. In one respect there is a change: biologists no longer despise the statistical method, which both these lecturers introduced into epidemiology. This enables Prof. Greenwood to give us an astonishing and rather consoling piece of information—the present loss of young Englishmen between 20 and 25 by military violence is 7,500 less annually than that of a similar age group in peacetime 100 years ago. The lecturer then went on to discuss what he termed "the authority of intention." A few years ago, praise of scientific research for its own sake would have been thought platitudinous, but recently men whose contributions to science, pure and applied, entitle their opinions to respect have maintained that scientific research should be restricted to the betterment materially and morally of mankind; and the satisfaction of intellectual curiosity, having no relevance to this, if not immoral is no better than harmless amusement. They strongly advocate planned research under authority; those who dissent from this faith see danger to scientific freedom. For this, control could be ideal only if we attribute a superhuman prescience to the planners. On such a system "Mendel's interest in peas might have seemed frivolous," though it has provided the scientific basis for genetics. It is indeed a commonplace of scientific history that discoveries made for the satisfaction of pure intellectual curiosity have often proved materially valuable to mankind.

Prof. Greenwood proceeded to a triumphant vindication of Galen's *De Temperamentis* by showing its modern application, among other things, to intelligence testing. "So the wheel has come full circle; temperament is an object of quantitative study. Galen may look down from Elysium . . . with a grim smile of approval." The lecturer concluded an address worthy of the tradition of his office by a glowing and well-deserved tribute to the work of the late Sir Walter Fletcher in organizing medical research unhampered by political considerations.

RADIOLOGY IN 1942

The 1942 Year Book of Radiology. Diagnosis: Edited by C. A. Waters, M.D.; Associate Editor, W. B. Fitor, M.D. Therapeutics: Edited by J. L. Kaplan, M.D. (Pp. 496; illustrated. 27s. 6d.) Chicago: The Year Book Publishers, Inc.

In spite of the difficulties resulting from the war the standard of excellence of previous years has been well maintained in the *1942 Year Book of Radiology* under the joint editorship of Drs. Waters, Kaplan, and Fitor. Radiodiagnosis occupies the first 265 pages and radiotherapeutics the remainder.

There are numerous articles of great interest in the diagnostic section. In the section on the osseous system, mention may be made of a method of removal of iodized oil after myelography in cases of protruded intervertebral disks, and of a survey by Thomas of vascular tumours of bone. In the respiratory section an account is given of Kerley's work on pulmonary changes in erythema nodosum, and other articles of interest are on pulmonary coccidioid infection, toxoplasmosis, and mass radiographic surveys of the chest. In the cardiovascular section the attention is caught by the work of Barclay and his co-workers on the foetal circulation, and Nelson's method of abdominal arteriography is given. A number of rare gastro-intestinal lesions are recorded, including haemangioma, syphilis, and Hodgkin's disease of the stomach, annular pancreas constricting the duodenum, and two cases of double gall-bladder. Gutierrez contributes an admirable survey of large solitary cysts of the kidney.

Although no epoch-making discoveries fall to be recorded in radiotherapy the section on that subject continues to give a complete survey of the work done in radiobiology and in radiotherapy of the various systems of the body. Once again the Year Book of 1942 is to be recommended to all radiologists as an abstract of the year's work in both branches of the subject.

Notes on Books

BALLINGER'S textbook *Diseases of the Nose, Throat, and Ear: Medical and Surgical* has become a well-established institution, which keeps itself alive by the regular issue of well-revised new editions. The eighth retains all the excellent features of its predecessors, and although it contains nearly a thousand pages has the advantage that the new shape and style make it lighter and easier to handle. There is, however, one chapter, which might be called ancillary rather than essential in a medical sense—on the singing voice—wherein such extraordinary views are expressed that they surely require reconsideration by an expert on the subject. The section on the ear remains a brilliant exposition of the subject. Henry Kimpton publishes the book in England at 60s.

Young Citizen, by A. E. MORGAN, is published as a ninepenny Penguin Book. Prof. Morgan is an authority on literature and education, and in 1938 he was commissioned by King George's Jubilee Trust to survey the whole field of adolescent activities. His report, *The Needs of Youth* (Oxford), has become a classic, and this Penguin contains much of the material in a shortened form, together with an account of developments which have taken place since the war. Most of its content is fact, but his opinions are founded on long experience and keen observation. The book is a very handy introduction to the larger work, and indeed to the whole social problem of adolescence.

Denture Base Readjustment, by H. HIRSEKORN, is published by John Wright and Sons at 10s. 6d. It is the contention of the author of this small book that many worn-out and ill-fitting dentures with vulcanite or plastic bases can be made useful and comfortable again by relining them. There is no doubt that this can be done at times and may save the patient the cost of a new denture, but experience teaches that most dentures which are unsatisfactory are best remade from the beginning. The idea of using the old denture as a tray for a new impression is well known, but the author gives some helpful suggestions for the chairside technique and stresses the use of the old original gutta-percha for the purpose. This book is for the dental surgeon and mechanic; but the general practitioner is asked to advise on most things in heaven and on earth, and it is well for him to know that many ill-fitting dentures can be made comfortable.

The Proceedings of the Cardiff Medical Society for the session 1942-3 have been printed for the Society by William Lewis (Printers) Ltd. of Cardiff. The volume opens with Dr. A. W. B. Loudon's presidential address, and there are four other papers, including one on "The Mayos" by Mr. N. L. Barrett; also reports of clinical meetings and discussions.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 13 1943

PSYCHIATRY AND SOCIAL MEDICINE

The emphasis recently placed on the social aspects of medicine by the creation of a chair in this subject at Oxford is reinforced by the disturbing revelations made by Titmuss that the rate of infant mortality among the poorer classes in this country was the highest in the civilized world between the two great wars. Such a shameful state of affairs—the death rate in Glasgow is higher than it is in Tokio—should not be tolerated if we are to hold up our heads. But it would be quite wrong to regard this as primarily the responsibility of doctors. As Lord Dawson pointed out in his Presidential speech to the British Medical Association on Sept. 22, the medical profession in its concern about such things got little support from the Government until only a year or two before the war. Not doctors by themselves, but only doctors working under the auspices of an enlightened health policy, which recognizes the enormous importance of environmental conditions as factors in disease, will ever produce the necessary results.

There is one branch of medicine in particular where the influence of social factors has been clearly perceived in practice as well as in theory for a long time. Psychiatry and social medicine have a very large mutual overlap, as was recognized by the Royal College of Physicians of London in issuing together on Oct. 29 the interim reports by its special committees on these two complementary subjects, one of them under the chairmanship of Prof. D. K. Henderson, whose annual reports from the Royal Edinburgh Mental Hospital have consistently stressed the social aspects of mental illness. The way is long past since psychiatry was regarded as the study of diseases; in fact alone of the medical disciplines as psychological medicine adopted in its very terminology the notion of "reaction types." Even in the largely constitutional disorders the share of the environment was recognized so that it became no longer customary to speak of a mental disease but of a "schizophrenic" or "manic depressive" type of reaction. It was even conceived that some mental disorders are the outcome of progressive maladaptation, over a period of years, to the social environment. This has long been the point of view of the psychiatric philosophy designated by the rather unattractive term "psychobiology," or the science of the individual personality conceived in terms of his heredity, his history, and the environmental influences to which he has been subjected. Much may be forgiven aesthetically to a terminology so practically comprehensive. But it has been in connexion with the so-called "functional nervous disorders," the "neuroses," or, more technically, the psychoneurotic forms of reaction, that social considerations have forced themselves upon the psychiatrists' attention, and this not only because of the Freudian discoveries

of the part played by the early family setting in providing the foundation for neurotic developments later, but for the repeated "common-sense" observation of the sharp unsatisfactory personal relationships to other people under contemporary circumstances in producing psychological health. Faced with such problems, psychological medicine found itself in need of a special kind of social worker—psychiatric social worker, trained not only in social work but in the significance of personal factors in the production of ill-health.

In the domain of physical disease itself psychology, as the name implies, has learned to look for some of the causes of such conditions as asthma, skin diseases, duodenal ulcer, hyperpiesis, and the not only in diet or endocrine disorders or infection but in personal conditions producing anxiety, insecurity and all the other painful emotions to which humanity is a prey. It follows that psychiatry is especially interested in schemes for "rehabilitation" or restoration of the individual into useful society. The report of the medical director of the Cassel Hospital for Functional Nervous Disorders for the year 1942 is largely devoted to this topic. Dr. C. H. Rogerson points out that the definition of rehabilitation given in the Tomlinson report is very unrepresentative of the attitude of modern medicine. "Rehabilitation in its strictly medical sense means the process of preventing or restoring the loss of muscle, restoring the full functions of the limbs, and maintaining the patient's general health and strength. (This is from special rehabilitation treatment required for physical diseases such as tuberculosis.)" The Cassel Hospital seeks to clothe this still meagre skeleton with something of a higher level of integration than muscle and peripheral nerve.

The period of transition from hospital, especially from a psychiatric hospital, to real life is a crucial one, for which few special arrangements exist to-day. The Cassel Hospital report suggests an intermediate type of hospital or hostel largely run by the patients, supervised by a trained nurse, and with only occasional medical supervision, because such a place would be principally concerned with occupation and recreation as a step towards the outer world. It is conceivable, however, that the extended use of psychiatric social workers in the community in paving the way for the patient in his home and at his place of employment might make some of this organization superfluous. The report also stresses the importance of work in maintaining the stability of the individual, not simply because of the definite rewards of work but because of the interest it may bring and because of the degree to which anyone's self-respect is involved in having a job. The report points out that it is probable that war work has been of appreciable benefit to ex-patients who in peacetime would probably have relapsed in the absence of a job, and it is reasonable to assume that it may have prevented other people from falling ill. The possibility of using existing organizations to help the resettlement of ex-patients in civil life is illustrated by experience of the usefulness of Labour Exchanges working in collaboration with the Cassel Hospital, and also of the value of a sympathetic attitude on the part of employers. Some psychiatric clinics have in the past

invoked the aid of vocational advisers so as to ensure that the patient will be placed as suitably as possible in industry. The experience of the Cassel Hospital suggests that the existing Labour Exchanges would be satisfactory in this way, especially as they have the advantage of being not only able to advise but able to produce an actual post of employment. There will, however, always be a proportion of people in whom more specialized vocational advice will be desirable, in which the psychiatrist must sometimes take his share of responsibility.

It is a relief in these days of expensive schemes to find that the report envisages the better use of existing facilities so far as possible, rather than the creation of new ones. Even the suggestion of an intermediate hostel might be met by ensuring that the staff of existing homes and hostels had some training in the social aspects of psychiatry. The new National Provisional Council for Mental Health has in fact begun educational work of this general kind in connexion with children's homes, and there is every reason to suppose that it can be extended to those having the care of adults. In similar vein the report deprecates the creation of "rehabilitation" specialists among doctors, pointing out that the more a doctor can carry responsibility right through a case the better. It suggests that specialism of this kind might be confined to ancillary services, such as occupational therapy, instruction in physical training, and specially trained nurses in charge of convalescent homes. The report is a stimulating effort to integrate the specialized services that can be given by a special hospital with the needs of the community. A psychiatric hospital is no longer simply an "asylum" or retreat: it is a "hospital" in the ancient sense—a guest house for those ultimately on their way back to real life.

CHEMOTHERAPY OR SERUM FOR SCARLET FEVER?

What is the appropriate special treatment for the acute stage of scarlet fever? Is it chemotherapy or serum, or both, or none? It is generally agreed that chemotherapy alone has no effect on the primary toxic phase, but there is some difference of opinion as to its effect on the incidence of complications. Streptococcus antitoxin, on the other hand, given in adequate dosage and by an appropriate route, undoubtedly neutralizes the initial toxæmia and so may indirectly prevent or reduce complications. In a discussion¹ at the Fêver Hospital Medical Service Group of the Society of Medical Officers of Health in January, 1939, the consensus of opinion as summarized by Mitman was: "For mild cases treated at home, no antitoxin or sulphanilamide; for mild cases admitted to an open ward, antitoxin intramuscularly; for severe cases, antitoxin intravenously; for complications, sulphanilamide." In the intervening period antitoxin has been considerably improved by developments in the protein-digest method of concentration, and the potency and range of chemotherapy have also been strengthened, notably by the introduction of sulphathiazole.

Mitman's summary, *mutatis mutandis*, would still probably meet with general acceptance in this country. The

opposing view—that sulphanilamide and not serum should be adopted as a routine treatment for scarlet fever—has been put forward by Neukirch and his colleagues² from Copenhagen, as a result of a study of some 300 cases so treated in 1940, with serum-treated and untreated controls. The type of scarlet fever was mild. Sulphanilamide was given for eight days from admission, in dosage varying from 1.2 to 3.6 g. daily according to age. The serum used was not streptococcus antitoxin; it was an "anti-scarlet fever streptococcic serum" prepared by the State Serum Institute "in such a manner that it has a high and polyvalent content of antitoxin and bacterial antibodies." This product seems therefore to be equivalent to a mixture of antitoxin and of streptococcus serum, and its potency in antitoxin units is not stated. Further, it was not a concentrated but a "native" or natural serum, and was accordingly given in dosage much higher than is used in this country—20 to 60 c.cm. intramuscularly or intravenously. (As a corollary it should be noted that no less than 63.9% of the serum-treated patients suffered from serum sickness and 1% from serum shock.) Such a serum is very different from the antitoxin now in use in this country and in the U.S.A. The main results of the study were: (1) except in the low age group 0–3 years (an important exception) sulphanilamide significantly reduced the bacterial complications as compared with the controls, and especially otitis and mastoiditis; (2) the "anti-scarlet fever streptococcic serum" was ineffectual in preventing complications. In assessing their results the authors have paid little regard to the different aetiology of early and late bacterial complications of scarlet fever treated in open wards. It is now well known that after the first two or three weeks bacterial "complications" under these conditions are nearly all ward reinfections.³ Some degree of protection against them is probably afforded by the use of sulphanilamide, but only during the period of its administration or a day or two thereafter—that is, in the case of this study, ten days at most from admission. Similarly with serum some protection is afforded for two to three weeks from the date of injection, at all events with antitoxin. In this study the average duration of hospitalization was 33.2 days in the sulphanilamide series and 34.8 in the serum series. With both treatments, therefore, the patients would be vulnerable to ward infections during at least the later weeks of their stay in hospital, and this constitutes an unassessed factor which might operate in variable degree in the two series. Nevertheless, there seems to have been a significant fall in the incidence of otitis in the age group 4–14 years in the sulphanilamide series, where it reached the low level of 1.0% of 200 patients, compared with 8.9% of 192 patients of these ages in the serum series. The figures are rather small, however, and they are more favourable to sulphanilamide and less favourable to serum than those obtained by the generality of observers.

Serum or sulphonamide treatment of scarlet fever in hospital constitutes only one factor in the prevention of complications. Other factors of paramount importance are (1) the control of streptococcal and other infections in a

¹ *Lancet*, 1939, 1, 327.

² *Acta med. scand.*, 1943, 13, 11.

³ Allison, V. D., and Brown, W. A., *J. Hyg., Camb.*, 1937, 37, 153.

ward full of highly susceptible young children; and (2) the shortening of the period of isolation of uncomplicated cases down to three weeks or less with the same object. The former problem can be attacked in various ways, but in practice is still unsolved. The latter has been shown to be practicable when the disease is mild, even with non-serum-treated cases,⁴ but is most easily achieved when antitoxin is given in effective dosage in the acute stage. The combination of effective antitoxin by the intravenous or intraperitoneal route,⁵ or in large doses by the intramuscular route,⁶ with a short isolation period of 2 to 3 weeks has produced in several large and controlled series a significant reduction of complications, including otitis media. Sulphonamides are auxiliary to antitoxin and their exact role is still unsettled. Their prophylactic use, if the effect is to be complete, involves a period of administration not merely of eight days but of several weeks, as Neukirch and his colleagues indeed point out. This is a rather formidable undertaking; a close watch has to be maintained to avoid serious toxic effects, and there is the disadvantage that when a bacterial complication actually occurs its effective treatment by sulphonamides may be debarred. For these reasons sulphonamides are perhaps best employed at present in the immediate treatment of bacterial complications as soon as they appear. There is no clear evidence that better results can be obtained in hospital-treated scarlet fever than by the combination of (1) a potent concentrated antitoxin in the acute stage, (2) sulphonamide treatment of bacterial complications at their earliest appearance, and (3) a period of isolation of three weeks or less for uncomplicated cases.

TREATMENT OF EXPERIMENTAL HYPERTENSION

The lowering of experimental hypertension in dogs after the injection of renin was reported by Wakerlin and Johnson in 1941,⁷ and they have now described further experiments the results of which deserve attention.⁸ In their first paper they showed how the blood pressure of their dogs had slowly returned to normal levels during a series of daily intramuscular injections of partially purified dog renin. Now they report that after the cessation of the injections the blood pressure slowly returned over a period of months to its previous hypertensive levels, but in three out of four dogs it was possible to lower it again by a second course of injections. Similar treatment for three months before and three months after constriction of the renal arteries prevented a rise in blood pressure in six of fifteen dogs; ordinarily the operation is 99% successful. The effect was permanent in some cases, but in others the blood pressure slowly rose after the end of the treatment. The mechanism of these prophylactic and therapeutic effects is not apparent, and it may rest on substances other than renin. Extracts of liver and inactivated renin preparations were without effect, but the renin extracts which were used were far from pure, and it may well be that in the process of rendering renin inactive another principle is also destroyed. Antirenin activity was demonstrated in the serum in some cases, but it is improbable that its presence is the explanation, because there was no constant relation

between the times of its appearance or disappearance and the changes in blood pressure. Moreover, it appeared in dogs which became hypertensive and was not found in others which did not. Discussion of other hypotheses will have to wait on confirmation and expansion of these experimental results. There are many points which suggest that the method may finally be of clinical therapeutic value if the first successes are confirmed. The dose of extract is the equivalent of one gramme of fresh kidney cortex per kilogramme of body weight per day, which is small compared with that used in other therapeutic attempts. The intramuscular route is easier than the intravenous. There are no toxic effects; appetite in the dog remains good, weight constant, and there is no change in the urine or in the blood urea. The beneficial effect persists for a considerable time after stopping the injections. Despite this, much experimental work needs to be done in animals before the treatment is applied to man, and, though it is full of promise high hopes of its clinical value would be premature.

ALCOHOL AND AVITAMINOSIS

The nineteenth Norman Kerr Memorial Lecture, under the auspices of the Society for the Study of Inebriety, was given by Dr. A. Ninian Bruce, his subject being "Alcohol and Avitaminosis." The lecture was a masterly discourse addressed largely to a lay audience, on the recent contributions of medical research to knowledge of the effects of alcohol on man. Dr. Bruce recalled that the direct action of alcohol was first described in 1787 by Lettsom in a paper to the Medical Society of London. The action on the nerves was to create what Lettsom called a neuritis. For many years it was accepted that the only action of alcohol was a direct one on the tissue cells containing fat. The nerve cells were particularly rich in certain fatty substances and as alcohol passed through them it was absorbed in the lipid matter, thereby disorganizing the cell function. With the work done on the isolation of vitamins—substances which the tissues could not synthesize and which acted as catalysts in helping ordinary food factors to be utilized—attention was drawn to the indirect action of alcohol. People with acute alcoholism had been found suffering from beriberi or pellagra, or both. The neuritis in beriberi appeared to be identical with that in alcoholism. In an American experiment a number of patients suffering from alcoholic neuritis were taken; some of them were continued on the same large amount of alcohol as they had been taking before, and others were deprived of alcohol; both groups were given large quantities of vitamin B, and both recovered at the same rate. These patients owing to their consumption of alcohol had begun to develop stomach trouble and had "gone off" their food ending by replacing food with strong drink, so that they were living upon alcohol, and were actually suffering from a deficiency disease due to a disturbance by alcohol with the intake of normal food.

One of the special troubles known to occur in chronic alcoholism was a liability to serious heart affections, with sudden death from heart failure. This was also the special characteristic of the beriberi cases. The withholding of vitamin B, not only deprived the nerve tissues of something they needed but also had an effect on the cardiovascular system, and there was now recognized a special form of heart trouble entirely due to the lack of vitamin B, and irresponsive to ordinary heart drugs; this occurred in people who, whether from poverty or alcohol were deprived of it. The vitamin had a direct effect on metabolism owing to its catalytic action. The question

⁴ Gordon, J. E., and Badger, G. F., *Amer. J. publ. Hlth.*, 1934, 24, 438.

⁷ *J. Amer. med. Ass.*, 1941, 117, 456.

⁸ *Amer. Heart J.*, 1943, 25, 1.

whether alcohol was a food opened up a controversy, but alcohol did not contain any vitamin and in no way helped to store up energy in the tissues. It had to be burned up in the tissues in the same way as carbohydrates. The oxidation of sugars to give the tissues a regular supply of energy took place in a number of stages. At the end of the process lactic acid was formed and was broken up by catalytic action into the simpler form of pyruvic acid, beyond which oxidation could not be carried further. If there was an absence of vitamin B the process of normal carbohydrate oxidation appeared to be interrupted at about this three-carbon-molecule stage, resulting in the metabolic disturbances and the abnormal functioning of the nerve cells seen in deficiency diseases.

Dr. Bruce ended his lecture by giving a definition of life in biochemical terms as any molecular system which could metabolize itself and was able to increase its molecular energy. The "life stuff" might be said to consist of a series of molecular systems working in harmony with each other. In order that those systems might remain in existence dynamically they required in infinitesimal amounts a large number of additional substances or factors. Among these substances were the vitamins which must play their part as catalysts in the continued existence of the "life stuff." When this was realized it would be seen how delicately life was poised, and how a powerful agent such as alcohol by interfering with this fragile mechanism rapidly brought about serious instability.

BLOOD IRRADIATION THERAPY

X rays and ultra-violet light are widely used in medical treatment, and attempts have lately been made to replace direct exposure, which may be inconvenient, by the administration of substances which have themselves been activated by exposure to the rays. The rationale lies in the fact that the energy state of a molecule can be altered by irradiation, as, for example, by simple heating. In regaining its original state the molecule then produces an emanation which may be similar to that which activated it. In a rather different way, by bombardment with highly charged particles in the cyclotron, it is possible so to alter the phosphate ion, for example, that it itself becomes radioactive. Irradiated sodium phosphate has been used in the treatment of leukaemia, and it is likely that the distant changes observed after direct irradiation of the leukaemic spleen are brought about in the same way, some molecules in the spleen being activated by the rays and then carried in the blood to distant organs. The difficulty of carrying out running repairs to x-ray plants in wartime and the fact that the cyclotron is not available for general use make the treatment of these patients a perpetual problem. Eidenow's¹ account of the effect of giving the gas radon to rats and rabbits by the intravenous route is therefore of current interest. He describes a simple method of dissolving an amount of radon of known radio-active power in a few millilitres of citrated blood. He gave this radon solution intravenously to the animals in lethal and sub-lethal doses, and carried out frequent blood counts until either death or recovery took place. Eidenow observed an initial leucopenia, followed by a slight leucocytosis in the animals which survived. In the fatal cases there was a progressive leucopenia, and the changes at necropsy could not be distinguished by him from those found when a lethal dose of radium had been applied as a plaque to the skin. Given a supply of radon, this is a straightforward technique apparently capable of quantitative control. Its

applicability to human beings might repay investigation at the present time.

Another type of irradiation therapy is described by Miley,² who used a machine known as the "Knott haemo-irradiator," by means of which it was possible to transfuse patients with blood which had been exposed to ultra-violet light a few moments previously. He remarks that ultra-violet rays are bactericidal *in vitro*, and can detoxicate snake venom, diphtheria toxin, and a number of other poisons, and claims that irradiated blood has a similar effect. He tried his treatment on a number of patients with chronic and acute sepsis, some of whom had failed to respond to sulphonamide therapy, and, on the basis of relatively few observations, records bactericidal, detoxifying, vaccine-like, and de-photosensitizing effects. There are many clinicians who hold the belief that "septic patients" benefit from small transfusions of fresh blood, and injections of whole blood have been used in a variety of septic and allergic states. A careful reading of Miley's paper does not convince one that the blood is any more effective for being exposed to ultra-violet irradiation or that makers of scientific apparatus could properly be employed in wartime in manufacturing "haemo-irradiators."

DICUMAROL AND SALICYLATES

Analysis of the chemical degradation of the anticoagulant drug dicumarol [3, 3'-methylene-bis-(4-hydroxycoumarin)] shows that it gives rise to salicylic acid. Moreover, a study of the physiological activity of various analogues of dicumarol has revealed that only those compounds show anticoagulant action which theoretically might yield salicylic acid or an o-hydroxybenzoic acid derivative on degradation. Link and his colleagues³ have now gone on to show that when single doses of salicylic acid are administered either by mouth or intravenously to rats maintained on a basal artificial ration low in vitamin K a temporary hypoprothrombinaemia can be induced, comparable in all respects to that caused by 3, 3'-methylene-bis-(4-hydroxycoumarin). They also indicate that these observations are reproducible in man, even when the diets are not restricted. The significance of the results in clinical medicine is not yet clear. The production of haematemesis by aspirin is generally agreed to be due to local irritant action on the gastric mucosa.⁴ Apart from this, the occurrence of haemorrhagic phenomena in patients under treatment with salicylates must be rather rare. More important, perhaps, is this new approach to the poorly understood problem of the beneficial therapeutic action of salicylates. It is tempting to think that an anticoagulant might prevent the formation of fibrinous nodules and vegetations; but this seems unlikely, for dicumarol has proved wholly unsuccessful in subacute bacterial endocarditis, and there is little evidence that salicylates hinder the formation of nodules and vegetations in acute rheumatism. It is perhaps more to the point to note that both the salicylates and cinchophen have a toxic action on the liver. Hench⁵ has maintained for some years that chronic arthritis is relieved during an attack of jaundice, and perhaps one day we may find a unity in these therapeutic and toxic phenomena.

The next session of the General Medical Council will open on Tuesday, Nov. 23, at 10 o'clock, when the President, Sir Herbert Lightfoot Eason, will take the chair.

EIGHT YEARS' EXPERIENCE OF A MINIATURE STATE MEDICAL SERVICE

BY

EDWARD THOMSON, M.B., Ch.B.

JOHN HAMILTON, M.B., Ch.B.

MAURICE CURRAN, M.B., Ch.B., D.P.H.

WILLIAM POOLE, M.B., Ch.B.

AND

JOHN ORR, M.B., Ch.B.

It has seemed to us appropriate, in view of the attention now being given to the establishment of a comprehensive medical service and the controversy arising therefrom, to give a brief account of the whole-time outdoor medical service, functioning in Glasgow, of which we are members.

This service was brought into being in 1935 on a whole-time basis when the industrial depression threw very large numbers of persons on the Poor Law, and it was to the Poor Law that they had to look for medical attention and hospital treatment. It may be explained that, under the Local Government Act of 1929, the powers and duties of the then Poor Law authorities were transferred to the local authority, which in turn remitted the hospital and medical services so transferred to the Committee on Health, so that the outdoor medical service developed as a function of public health. Steps were taken in 1936 to remodel the former part-time service, to provide it with new and up-to-date clinics, and so appoint a whole-time staff of doctors and nurses operating at and from 13 clinics throughout the city. The following is a brief account of the staffing, functions, and administration of the medical service thus established.

Functions and Administration

Growth and Staffing of the Clinics.—By 1940 the 13 clinics, most of them in new *ad hoc* buildings, were staffed by 30 whole-time district medical officers, 26 nurses, 27 female clerks, and 15 dispensers; in addition there were 9 part-time district medical officers—making a staff of 107 in all. The duties comprise medical examination and treatment at these centres, along with domiciliary treatment of the patients eligible under the scheme, while the services of the nurses are available at the clinics and for visiting patients at home. The number of doctors attached to and working from each centre varies from one to four.

Scope of the Service.—The medical facilities provide a continuous 24-hours service for seven days a week. Four members of the staff undertake only evening, night, and week-end duties for periods of three months in rotation. Thus all enjoy a degree of social freedom unknown to those of us who were formerly in general practice. It may be useful to give the following table showing the manner in which these rosters are arranged:

for Evening, Night, and Week-end Duty during April,
May, and June, 1939

	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
1	Day off	p.m. p.m. 5 11	p.m. p.m. 5 11	p.m. p.m. 5 11	p.m. p.m. 5 11	p.m. p.m. 2 11	p.m. p.m. 2 11
2	p.m. p.m. 5 11	Day off	p.m. p.m. 5 11	p.m. p.m. 5 11	p.m. p.m. 5 11	p.m. p.m. 6 11	p.m. p.m. 4 11
3	p.m. p.m. 5 11	p.m. p.m. 5 11	Day off	p.m. a.m. 11 9	p.m. a.m. 11 9	p.m. a.m. 11 9	p.m. a.m. 11 9
4	p.m. a.m. 11 9	p.m. a.m. 11 9	p.m. a.m. 11 9	Day off	Day off	p.m. p.m. 12.30 6	a.m. p.m. 9 4

No. 1, Dr. A., starting Saturday, April 1, 1939, 2 p.m.—11 p.m.
No. 2, Dr. B., " " " " " " 6 p.m.—11 p.m.
No. 3, Dr. C., " " " " " " 11 p.m.—9 a.m.
No. 4, Dr. D., " " " " " " 12.30 p.m.—6 p.m.
During the week starting Monday, April 3, No. 1 becomes No. 2, No. 2 becomes No. 3, No. 3 becomes No. 4, No. 4 becomes No. 1; and so on each succeeding week until June 30 (or such date as may be decided upon later).

During the summer holiday months this arrangement is suspended, the medical officers undertaking evening, night, and week-end duties in a rota in addition to their normal day as well as providing relief one night each week to their colleague who has been delegated to overnight hours. The system is made doubly secure by a reserve medical officer being available outside normal working hours. On the occasion of public holidays the clinics are closed and a skeleton medical and nursing staff meets the urgent demands of the community, and does such revisiting as has been notified by district medical officers to the central office as being desirable.

Services at the Clinics.—The clinics provide adequate consulting and treatment facilities, with waiting-room, clerical accommodation,

and nurses' room, along with a dispensary and waiting-space for patients having their prescriptions dispensed. The principle underlying this arrangement is, of course, to assist the medical work by providing the doctor with the three essential requirements—namely, the services of a nurse, a clerk, and a dispenser. In the construction of clinic premises there are two cardinal points which might with advantage be stated. In the first place, where considerable numbers of patients are dealt with, waiting-room accommodation must be generous, as many patients attend with relatives or friends. This applies even although the staff may be large and the work is carried out expeditiously. Secondly, the clinic should be so designed that circulation of patients between entrance and exit is ensured, crossing and recrossing being avoided. The drug dispensary or pharmacy should be situated at the exit. If separate entrance and exit cannot be arranged, then attention should be paid to the provision of corridors of adequate width.

Nursing Service.—It was realized that in domiciliary treatment the work of the medical officer would be incomplete and ineffective without the assistance of nurses. They are engaged on the same basis as health visitors, and all recent entrants possess the health visitor's certificate, which provides them with a background of social knowledge and experience. It was felt that the possession of this certificate would add to the value of the service, as a good deal of the work lies in the supervision and treatment of young children who come under the care of the medical officers. The nurses are able to keep the more chronic types of patient under frequent observation at home, and also assist at the clinics with dressings, treatment, and other routine work.

Dispensing of Medicines.—A dispensary, fully equipped under a qualified pharmacist, is provided at each clinic. The drug dressings, and appliances come from the central drug store of the Public Health Department, which was established some years ago to supply all the clinics and hospitals of the department. The advantages of a local dispensary of this kind attached to a clinic are obvious. Beyond clinic hours and for emergencies, a contract similar to that under national health insurance has been entered into with the chemists of the city.

Hospital and Laboratory Liaison.—All the hospitals of the local authority have been appropriated as public health institutions, and have been upgraded, enlarged, and expanded, so that a close liaison with them and with their specialist services is a matter of simple arrangement as regards both indoor and outdoor facilities. To assist admission to hospital where necessary and to allocate beds as between the general and special hospitals, a medical officer of the service is on duty at the hospital admission department of the Central Public Health Office, where there is a staff of removal clerks and a telephone exchange. A complete modern ambulance service, centrally located, works in conjunction with the central office, and a nurse accompanies each ambulance. The resources of the Public Health Laboratory, as also those at the hospitals, are available to the medical service.

Range of Duties of the Medical Staff.—The duties of the district medical officers consist of the care of the sick poor eligible for Poor Law relief, for allowances under the Unemployment Assistance Board, and the care of blind persons. They also act as public vaccinators, and fulfil the provisions as regards certification of lunatics and supervision of mental defectives required by the Lunacy and Mental Deficiency Acts pertaining to Scotland. Dependents of men on service with the Forces are eligible for attention from the medical staff. A.R.P. duties as medical officers to first-aid posts are undertaken, as also the examination of civil defence personnel on sick leave when reports are required. It is laid down that they shall perform such other duties as the medical officer of health may decide. It may be explained that the powers given to local authorities in England and Wales to provide clinics for the sick generally under the Public Health Act, 1936, do not apply to Scotland. This lack of statutory power in Scotland explains why the clinic service in Glasgow is restricted to the sick poor and other functions described.

Co-operation with Other Branches of the Public Health Service.—There exists a close association with the more special clinics of the local authority for the diagnosis and treatment of tuberculosis, with treatment of school children and pre-school children, and with ante-natal and post-natal work. Such patients are treated and supervised at home when they are unable to attend at their appropriate clinic centres. As an example of co-operation, the services of the medical and nursing staff were fully utilized during the recent mass vaccination against smallpox. They assisted in the staffing of the 25-vaccination centres and in house-to-house vaccination of contacts in addition to their routine work. Again, the staff took part in the scabies campaign, supervising the special treatment centres established for the purpose.

Medical Certification.—Before relief is given, the Welfare Department requires a medical certificate. Also, the Unemployment Assistance Board provides allowances for extra nourishment where there is a possible medical reason for so doing. These allowances are paid in cash, so that to many recipients a medical certificate is

respect of a dependant may mean an increase in the scale of payment. Certificates are also required where there is a doubt as to fitness for work, or otherwise, of a patient, the case then being referred to a district medical officer. Since these certificates are given "on soul and conscience" they demand care and accuracy in their completion. From his unique position of independence the district medical officer is entirely freed from all influences likely to prejudice his judgment.

Medical Boards.—It is obvious that, particularly in cases of application for monetary relief, divergence of medical opinion may occur between the district medical officer and the patient's own doctor. To deal with this difficulty patients are referred to Medical Boards either by the district medical officer or by the Welfare Committee. The Medical Board is constituted by one of the district medical officers and a senior medical officer on the hospital staff, and meets at one of the Corporation hospitals. In the case of patients referred to the Medical Board who are in receipt of monetary benefit from national health insurance, an endeavour is made to obtain the regional medical officer's report of his examination if the patient has been previously examined by him. Similarly, the regional medical officer may obtain the findings of the Medical Board should he be called on to deal with a patient previously examined by the board. Where the patient has no other medical attendant and the district medical officer has the slightest doubt as to his fitness for work, examination by the board is arranged. In the case of patients referred for examination by the Unemployment Assistance Board, the Medical Board is constituted by a regional medical officer and a district medical officer.

Hospital Accommodation.—Reference has already been made to the transfer and reorganization of the Corporation general hospitals. While formerly these were solely for the use of the sick poor, and though that remains their primary purpose, they are now available to the entire community, and without application to the Welfare Department. In spite of a policy of expansion, interrupted by the war, the hospitals are unequal to the demands made on their accommodation. The easing of this strain on accommodation has become a major function of the domiciliary nursing service. In this, as was to be expected, it is only partially successful, and a system of priority of admissions has had to be introduced. This duty is undertaken by the district medical officer, who assesses the urgency of the case, not only on medical grounds but also in relation to home circumstances. The war aggravated the position in three ways—i.e., restriction on building, the loss of a large number of beds in the general hospitals for civilian casualties, and the demand for man-power, which often left the patient without anyone competent to look after him. To overcome this acute problem an arrangement was made with the Department of Health for Scotland whereby emergency hospitals were, in part, made available.

As all patients are not suitable for admission to these emergency institutions—which lie outside the city—owing either to the special treatment required or to their inability to stand up to the longer journey, a process of selection by the district medical officers had to be adopted. It is interesting to note that admissions by certificate of district medical officers are forming a decreasing proportion of the total admissions. In other words, district medical officers are treating more of their patients at home, while private practitioners are tending to send more cases to hospital. Thus the hospitals are being used more and more by the general public.

Advantages of the Service

In the circumscribed area served by each clinic the location of the doctor is known. Accordingly, his services can be procured with the minimum of time and trouble. Continuity of treatment, which is greatly assisted by adequate and accurate clinical records, is one of the principal features of the scheme. Though a doctor is normally attached to one particular district, his absence may be occasioned by sick leave, annual vacation, or night-duty requirements. Under these circumstances the records prove their worth, together with the valuable store of information which the nursing sister places at the disposal of the relieving medical officer.

Though there is no free choice of doctor, judging from past experience and from information obtained from national health insurance statistics there is evidence that this is a relatively unimportant factor from the patient's point of view. Idiosyncrasies on the part of both patient and doctor will occasion difficulties from time to time, but there is little reason to doubt that with sympathy and tact these can generally be overcome, as they have been.

From the outset the advantages provided by the domiciliary nursing service were obvious, both to patients and to doctors. There is no doubt that this has satisfied a long-felt want on the part of the community, and the services of the nursing sister are now an indispensable feature in the social life of the

district. These services are linked to a variety of methods of health education, health preservation, and social activities generally. If the advantages to the family rather than to the individual are considered the improvement is very great. The community benefits from such a service. A steady flow of information as to the health of the people is provided, enabling changes to be made in those institutions affecting health. The number of hours lost by the staff through sickness is reduced by reasonable conditions of service.

The advantages are by no means one-sided. Compared with the lot of the general practitioner, who has to work in almost complete isolation, together with the fact that he is cut off from the hospitals, the impossibility of his taking an active part in postgraduate activities or his inability to obtain refresher courses in medicine, his lack of proper leisure, and, in many instances, his lack of provision for retirement, the lot of the district medical officer is indeed a favourable one. In the service in which we are engaged security of tenure and reasonable conditions of work have afforded opportunity for medical study. For instance, since the inception of the service, members have taken the following qualifications: one M.D., one F.R.C.S.Ed., and four D.P.H. Several members of the staff have been called to the Forces, so that the opportunities for postgraduate study have been curtailed.

Summary

We have described a whole-time medical service conducted on behalf of a particular group of the industrial population of a large city, a group among which problems of a medico-social kind most commonly arise. The service provides clinic, domiciliary, and hospital treatment. It meets the needs of its patients, runs smoothly and is flexible and capable of improvement and extension. Most of the doctors engaged in it are satisfied that it is a good service because in our view it carries advantages both to the patient and to the doctor. The work is congenial and unhurried except in time of pressure, while the doctor has the help of his colleagues and of a hospital service in the background for diagnosis and treatment. To the patient the services given are reasonably prompt and adequate. The function of this scheme is to look after the sick poor who are able to attend the clinics during the day. Its application to workers who require medical attention in the evenings would be a matter of administrative adjustment. In conclusion, we have described the scheme and given our views upon it; it is not put forward in the sense that it is a final solution of present-day problems, but rather as a specific contribution for consideration and criticism.

EDUCATION IN PSYCHIATRY

The poverty of training in psychological medicine in many of our schools is notorious; in few of them has the student had a proper introduction to the subject, and those schools that have tried to eke out the scanty resources available for teaching had little encouragement from the programmes of the medical curriculum.¹ The Committee on Psychological Medicine of the Royal College of Physicians of London in the interim report published on Oct. 29 deals solely with undergraduate education in psychiatry, which was the third of its four terms of reference. Its recommendations were printed serially in the *Journal* of Oct. 30 (p. 553) together with those of the related Committee on Social and Preventive Medicine.

UNDERGRADUATE TRAINING

The Committee on Psychological Medicine begins its report on this subject with a truism, a digest, and a pungent commentary. "Medicine has never been considered wholly a matter of physical disease: much of the illness which doctors have to treat, and some which they might succeed in preventing, is due to psychological rather than to physical causes; but in medical education little regard has been paid to this manifest truth. The medical student has commonly had, by the time he qualifies, a handful of demonstrations and lectures on psychoses, incidental teaching on the diagnosis and summary handling of psychoneuroses, and perhaps a cursory notion of psychological theories: anything further will depend on the individual student's enterprise or curiosity and on whether he has attended one of the very few medical schools where the systematic teaching of psychiatry is thorough. Such a state of affairs would not have continued unless there had been many who believed the present training to be adequate." After amplifying this to show how weak is the contention that the training is adequate and how tellingly it has been refuted during the present war, the committee

¹ See "Psychiatry at the Cross-roads," *British Medical Journal*, Sept. 11 1943, p. 531.

goes on to argue that, just as in medicine and surgery, the practitioner is less likely to undertake treatment which is beyond his competence or to neglect measures which are well within it if he has a solid, well-planned, limited but coherent course of clinical and systematic teaching in psychiatry. It cannot be taught solely by demonstrations and lectures, nor in one term or during only one year of the curriculum. Unless built upon a knowledge of what is normal it is as empirical and insecure as clinical medicine would be without physiology. So there must be normal psychology in the preclinical period, and the relevance of psychiatry to other branches of medicine cannot be appreciated unless it is being inculcated alongside them during the clinical period. Foremost among these other branches will be social medicine—and here the report links up with that of the other R.C.P. Committee. While recognizing that the syllabus it proposes will demand a greater share of the time of the medical student, the Committee on Psychological Medicine feels that any reorganization of the curriculum must take account of psychiatry as an integral and indispensable part of medicine. From this, it follows that every teaching medical school should have a department of psychiatry for both out-patients and in-patients, with an adequate staff and accommodation, in liaison with a local mental hospital as well as other local institutions.

The Pre-clinical and Clinical Periods

With regard to the teaching of normal psychology in the preclinical years it is emphasized that the object of training at this stage, as indeed throughout the medical course, should be to produce a good general practitioner and not a specialist in psychological medicine; it is more important to introduce the student to the subject and make him aware of its mode of approach and practical possibilities than to try and cover a wide field. He should, under guidance, visit schools, factories, courts, etc., where obvious psychological problems arise. At the beginning of the first clinical year there should be an introductory course on the psychological aspects of clinical work. A systematic course on psychiatry should extend throughout the clinical period, covering the whole range of mental disorder and mental deficiency, with constant emphasis on the social aspects of mental illness in all its forms, including the neuroses. An in-patient psychiatric unit, in the committee's opinion, is an essential part of every medical school. The three months' clerking in the psychiatric department should be combined with work in other special departments, preferably neurology and perhaps paediatrics. The committee accepts the view that neurologists and psychiatrists must work closely together, and suggests that in the teaching of psychiatry to undergraduates the psychiatrist should have the co-operation of the neurologist along lines that are mutually agreeable.

The committee puts forward a tentative syllabus for lecture-demonstrations on mental deficiency in the systematic course of instruction during the clinical period, prefacing this with the remark: "About one in every hundred of the population is mentally defective, and if the dull and backward are included the total incidence of intellectual retardation in the country is probably at least ten times as great." The place which mental deficiency has taken in the medical curriculum is by no means commensurate with its importance.

Psychiatry and Social Medicine

In conclusion, the committee maintains that the student needs to be taught both the social aspects of mental illness and the psychological aspects of social and industrial conditions, his attention thus being directed to the essential unity of medicine. In the psychiatric sphere much of the actual work of tuition and the organization of home visiting, etc., can be carried out by the psychiatric social workers (more of whom should be employed by teaching hospitals) and by almoners, working in close co-operation with, and under the general supervision of, the psychiatrist and his assistants. The committee recommends that the student's knowledge of normal psychology should be tested at the end of his pre-clinical period, and that in the finals there should be a separate examination in psychiatry, taken either at the end of the clinical period or earlier.

EFFECT OF WAR CONDITIONS ON MENTAL HEALTH

The first conference to be summoned by the Provisional National Council for Mental Health, which incorporates three bodies associated with mental welfare and also the work of the Mental Health Emergency Committee, was held in London on Oct. 29, and delegates from authorities under the Lunacy and Mental Treatment Acts and the Mental Deficiency Acts attended from all parts of the country. In opening the conference Mr. ERNEST BROWN, Minister of Health, spoke of the need for more out-patient centres, and, what was still more urgent, the development of child guidance clinics, which, he said, might be the means of saving many unstable and unbalanced children from developing serious mental trouble.

He attributed to the improvement in employment the fact that the stress of war had not led to any increase in the incidence of the more serious mental disorders. The experience of this country up to the present had confirmed that of Barcelona in the Spanish civil war that war stresses in themselves did not increase the incidence of psychosis. One of the problems confronting us as the result of the war was that of Service men and women discharged from mental units and neurosis centres. If they were not to become a burden to themselves and the community they must be given skilled help in adjusting themselves to civil life.

Dr. THOMAS BEATON gave an interesting account of the growth and development of the comprehensive mental health services of the local authority of Portsmouth. The principal factors were the setting up of a central mental treatment department to provide the necessary psychiatric social service, the formation of a mental treatment committee of the local authority to cover the whole field of mental and nervous disease and mental deficiency, and the use of the mental hospital for in-patient treatment. The mental hospital was visited daily by a psychiatrist, and the education authority and the school medical service were closely co-operating with the running of the ancillary child guidance clinic.

Sir FARQUHAR BUZZARD, who presided over the second session, expressed the hope that when the promised White Paper appeared it would be found that the Minister had arranged for a comprehensive medical service in which most of the money provided would be invested in a long-term policy of prevention. Mental and physical health could not be separated. Notable advances had been made in the diagnosis and treatment of all forms of nervous and mental disorder during the last ten years, but greater effort was necessary on the preventive side.

Experience in an English Rural County

Dr. J. S. I. SKOTTOWE described the effect of war conditions on mental health as instanced in the population of Buckinghamshire, where a careful statistical control had been maintained. In 1938 the incidence of the more serious mental disorders as judged by the numbers entering the county mental hospital was 7.7 per 10,000 of the population; in 1941 it was only 6.4, but it was higher (7.1) among those who had come into the county since the war started and lower (6.1) among the permanent population. The incidence of the less serious disorders (treated as out-patients and in their own homes, but requiring specialist attention) was 1.7 per 10,000 in 1938 and 2.4 in 1941, but the proportion of such patients subsequently requiring to enter a mental hospital fell from 23 to 13.2. Taking the gross figures for all degrees of mental illness requiring specialist advice, the incidence in 1938 in Buckinghamshire was 9.4 per 10,000, and in 1943, 13.9, but this was not entirely a real increase; much of it was accounted for by the upgrading of psychiatric services, the diminution of public prejudice against seeking advice about mental health, improved diagnosis, and extreme pressure of work of general practitioners. There remained a slight real increase, but the increase was in minor disorders, not in major ones. The most typical cases were seen at the beginning and end of occupational life, characteristically in girls in their teens and men in their seventh or even eighth decade. His conclusion was that war conditions did not increase the incidence of the more serious disorders, though they did probably increase slightly the incidence of the less serious ones.

Sir LAURENCE BROCK, chairman of the Board of Control, said that the first result of the war was a sharp rise in admission rates owing to the clearance of observation wards and also to the inability of families, on evacuation, to look after their old relatives. But before the end of 1940 admissions were below normal and had remained. The number of cases of neurosis had increased, largely explained by the severance of people from their normal surroundings. The increase was not of serious dimensions, but it was the absence of facilities for treatment of such cases which caused concern. Should there be a recurrence of prolonged unemployment after the war many people who had escaped a breakdown while the war continued were likely to swell the list of admissions to mental hospitals.

Speakers from Aberdeen, Bristol, and other areas gave similar testimony. Dr. DORIS ODLUM said that at her clinic a type of anxiety had been manifested, a reaction which had both a physical and a mental pattern. It was a prolonged series of stresses, and not an acute sudden stress, which caused a breakdown. Another discussion was on the residential school and its place in the education of defective and subnormal children. Mr. E. R. DAVIES, of the Berkshire County Council, described the work of a child guidance clinic which had been set up by his authority under the Mental Treatment Act. This clinic was the first of its kind in the country to employ two whole-time psychiatrists and a full staff of educational psychologists and psychiatric social workers. The scheme, which was intended to be a permanent, not a wartime, measure, was operating satisfactorily and could be recommended as a method of establishing child guidance clinics for moderately sized authorities.

Correspondence

Are Hospital Diets Adequate?

SIR.—In a recent publication of the King Edward's Hospital Fund for London, Memorandum on Hospital Diet, to which reference has been made in a leading article in this *Journal* (Sept. 18, p. 365), it is suggested that a daily diet yielding about 1,690 calories is adequate for a hospital patient weighing 70 kg. A daily requirement of 1,690 calories represents the "basal metabolism" of a subject of this weight. "Basal metabolism" is strictly defined as the energy output of a subject who is at complete rest under comfortable conditions and has had no food for the preceding twelve hours. If, therefore, we accept as our criterion the daily requirement of a 70-kg. man, it is clear that there will be no surplus in the proposed diet to meet the increase of metabolism above the basal level caused either by the specific dynamic action of the food taken (the resting metabolism is always increased during the absorption of food into the body) or by muscular movements, which will be made to an increasing degree as convalescence is established. Nor will there be any surplus to make good the wasting of the tissues which may have occurred in the earlier stages of the illness when the patient was unable to assimilate an adequate amount of food.

It seems to us, therefore, that if we adopt the criterion upon which the memorandum is based the proposed diet cannot be regarded as really sufficient, and we suggest that it might be wise to give the matter further consideration.—We are, etc.,

Mind and Stomach

SIR.—There would seem much to be said for a possible "anxiety" factor in the manifestation of peptic ulcer, although there are many cases in which this is not apparent and very difficult to elicit by ordinary examination. There seems also very little doubt—making all allowances for earlier and more accurate diagnosis by present-day methods—that the incidence of peptic ulceration has increased in recent years. But what is the explanation of the difference between the two sexes? The figures quoted by Sir Henry Tidy show that the ratio of incidence between men and women is in the region of 5 to 1. That there is such a striking difference must be the common experience of all who see large numbers of such cases. But the national and international environment during the last twenty-five years has been the same for both sexes, and it would be difficult to argue that women are less exposed to the ordinary stresses and strains of everyday life than men. If there is a strong psychical factor at work in the causation of peptic ulceration, why are women so relatively immune? If we could discover the answer to this question we might be able to make some substantial advance in the treatment of these cases, after-histories of which show how relatively unsatisfactory are the present methods, both medical and surgical.—I am, etc.,

London, E.C.1.

H. H. BASHFORD.

Sterility and Impaired Fertility

SIR.—The letter under this heading in your issue of Oct. 16 (p. 493) directs attention to the frequency of (physiological) sterility and to the need for an extension of facilities for its further investigation and treatment. With this part of the letter of your sixteen correspondents we are in agreement.

We do not, however, agree that "all available data strongly suggest that the barren and the very small family reflect lower fecundity rather than excessive unwillingness to reproduce." We believe that a definite pronouncement on these questions cannot be made until much more evidence becomes available. For example, we require to know the fertility-trends in the major social groupings and the variation in the size of families according to social and economic levels, by date of and age at marriage. These are data which can only be ascertained

by census inquiries. Meanwhile, there is much evidence that a major influence in the creation of the modern small family is voluntary restriction of fertility, and that this has had its origin in changed social and economic standards. Thus, so long as there is no adequate evidence of a difference in the innate fertility of different groupings, it would seem to be safe to assume, for example, that the small families of the professional classes are due to voluntary restriction.

From the demographic standpoint the central question at the present time is whether infecundity has increased in such a way as to play a part in the decline in fertility. At present there is no evidence to show that such an increase has played any part at all. There is no reason for thinking that fertility is any more affected by this cause now than it was 70 years ago, when the birth rate was over 30 per 1,000. In the effort to raise fertility, undoubtedly everything should be done to help parents who are involuntarily sterile; but the main object of policy must remain that of changing the social and economic conditions and the attitudes of normally fecund parents so as to favour the large rather than the small family.—We are, etc.,

Symptoms of Vitamin B Deficiency

SIR.—The studies in vitamin B deficiency by Drs. Clarke and Prescott (Oct. 23, p. 503) call for comment on several points.

1. The italicized list of symptoms common to psychoneurosis and vitamin B deficiency specifically omits diarrhoea. Even granting that occasional cases of pellagra are recorded as having constipation, diarrhoea is such a cardinal feature of the disease and so important in diagnosis that this deliberate omission seems quite inexplicable. Moreover, there is no account of the state of the bowels in the case records quoted.

2. With the general conception of a marginal diet, made quite inadequate by additional factors, as the cause of the symptoms in these cases few will disagree. Nevertheless I think the authors are too easily satisfied by this simple hypothesis; actual clinical experience suggests that some other factor must be at work to explain why some persons readily develop pellagra, and become chronic or relapsing, and others do not. I feel that Case IV, of eleven years' standing, illustrates this, and I would not be prepared to accept typhoid fever at some unstated time in the past as a material factor in malabsorption.

3. The occurrence of "symptoms usually regarded as psychoneurotic" raises, I agree, an important point in differential diagnosis. Nevertheless psychopathologically the distinction is not valid: it is only the significance of the symptoms that is distinctive. In kind they are indeed psychoneurotic, in the sense that they are reactive to an awareness, conscious or unconscious, of incapacity. The latter results in these cases from early organic cerebral change (as is witnessed by histopathological evidence and by the clinical features of chronic demented cases). It is surely a commonplace of psychiatry that the earliest manifestation of organic cerebral damage may be a purely "functional" syndrome long before detectable signs of the "organic syndrome" are evident.—I am, etc.,

Manchester.

G. H. H. BENHAM.

Wartime Diet for Peptic Ulcer Patients

SIR.—I should regard Sir Arthur Hurst (Oct. 23, p. 523) a formidable opponent with whom to cross swords on the subject of peptic ulcer were it not for three facts: (1) I have had a peptic ulcer in wartime and he, so far as I am aware, has not. (2) I am in the thick of the fray on the industrial front, and he, I note, writes from the quiet of Oxford, from which retreat I do not think he can possibly be aware of the difficulties under which industrial peptic ulcer patients labour, especially when their wives are conscripted into part-time employment, shopping is difficult, and domestic help unobtainable. (3) Such a sweeping generalization as "there is no food intrinsically bad for ulcer" I would hardly expect from one of Sir Arthur's eminence. Is this a new physiological principle? Are we all,

then, of the same digestive ability? Is the proverb, "One man's food is another man's poison," utterly inaccurate? Is it reasonable to pay no attention to a person's likes and dislikes, to what he can and cannot digest? I cannot in my present condition digest, among other things, the chocolate Sir Arthur mentions; it makes me feel sick. Must I nevertheless continue to try and absorb it?

I find that meat produces in me far more HCl than cheese, hence my suggestion of a temporary exchange. I find that milk alone in the few ounces at a time Sir Arthur advocates does not close my pylorus; I must have something solid to go with it, hence the suggestion for biscuits (now positively unobtainable in my area). There must be thousands of similar cases in the country all struggling along under a grave handicap, simply because no one has yet awakened to the fact that something ought to be done about it.

I agree that anxiety plays some part in the causation of ulcer and its recurrence, but intense and sustained mental effort and working under pressure are equally causative. There is no doubt that Davies and Macbeth were right in 1937 when they drew attention to the psychogenic factor in causation. I also agree that phenobarbitone is helpful, in fact essential, and I have obtained more benefit from the following prescription than from alkalis and adsorbents: sod. phenobarb. gr. viij, ext. hyoscyam. liq. ʒj, syrupus ʒj, aq. chlorof. ad ʒviij. Sig.: ʒij after breakfast and lunch and ʒss h.s. I fully agree that smoking is deleterious. It should be totally prohibited, not strictly rationed, and alcohol also should be forbidden.

I thank the doctors who took the trouble to reply to my appeal, and will write to them all personally as soon as I have time. Those who did write were all in favour of my suggestions, and those who did not were, I expect, much too busy even to open their *Journals*.—I am, etc.,

Harrow, Middlesex.

J. B. WRATHALL ROWE.

Psychiatry at the Cross-roads

SIR,—Doctors and patients too are indebted to Dr. W. Sargent for drawing attention (Oct. 9, p. 462) to the urgent need for better organization if there is to be any real progress in psychiatry. In supporting Dr. Sargent's forceful argument I agree with him that this is not an attack on individual superintendents. It is a criticism of an obsolete system. It is a plea for clinical freedom—a thing practically non-existent in county mental hospitals.

The reason for this state of affairs is obvious. Promotion in the mental hospital service is almost exclusively in the hands of administrators, whose tendency is to appoint as their assistant medical officers not colleagues but "yes men," who will render lip-service and who will avoid trouble at all cost—at the cost of their patients' welfare. The A.M.O. who puts clinical progress before the personal interests of his chief is unpopular; he is passed over in the struggle for promotion, and he seldom has access to the hospital committee, even though he may have ideas and skill which would benefit the hospital. A man with such ideas is snubbed, the medical superintendent regards him as a rival, and the hospital suffers.

The best type of medical man is not attracted to this sort of institutional work for one definite reason: this reason is the absence of the professional freedom enjoyed by senior staff in voluntary hospitals as contrasted with their colleagues in mental hospitals, where the superintendent is technically in charge of all the patients and is the immediate "boss" of the whole of the medical staff. If the mental hospital service is to develop it is essential that medical men should be attracted to it as doctors rather than as administrators, who now get all the highest-paid jobs.

The medical superintendent who sees a personal insult in the efforts of an A.M.O. to improve the hospital will not build a progressive team. His assistants must either subordinate their highest ethical ambitions or else retire from a position in which their noblest ideals are rendered sterile. This means leaving the service to undertake real medical work elsewhere. And such a step requires considerable courage. The majority of medical officers, being entirely dependent on the administrator's good will, take the easier course and become "medical clerks" in the hope that one day they will achieve a comfortable and secure position at a superintendent's desk.

How can this terrible handicap to psychiatry be averted? To begin with, all staff appointments should be made by committee whose members will not be afraid to override, if necessary, the personal likes and dislikes of the administrator. Such a committee would evaluate a candidate's worth not only as a technician but first of all as a man. Existing arrangements are often nothing but "eye-wash" to enable superintendents to tell patients, their relatives, the Board of Control, or visiting committees too, that modern scientific facilities are available. It is to be hoped that future mental hospital committees will be guided by something more fundamental than a diploma or two—by the individual doctor's skill in treatment, teaching, and research. Then, and only then, will the mental hospital take its proper place in the life of the community.—I am, etc.,

Wimborne.

J. STEPHEN HORSLEY.

Iodine Deficiency

SIR,—You are probably aware of the fact that some of our best-known of our medical authorities are now impressed by the fact that iodine deficiency in our ordinary food is evident and that in certain districts steps are being taken at this moment to improve the situation by the administration of iodized salt. I understand that there will be an early announcement on this subject in the medical press.

My object in writing this letter is to point out that I have been engaged during the past 14 years in urging that steps should be taken in this matter, but my various articles have been ignored, at least in this country. In 1933 I published a pamphlet on "The Problem of the Prevention and Treatment of Disease," concluding it with these remarks: "The leading nation from the point of view of health will be that which realizes the value of salt iodization and puts it into general practice." This pamphlet was widely distributed in this country and abroad, and early in 1934 I received a request from a German agency in London to let them have as many copies of this pamphlet as could be spared. This request was duly complied with, and I was informed that they had been forwarded to Berlin, Leipzig, and Munich.

In Jan., 1939, an article written by Dr. F. Fischler, director of the German Research Institute of Food Chemistry, Munich, appeared in the *Deutsche Medizinische Wochenschrift*, in which he gave an account of an extensive series of experiments carried out on people in certain parts of the Rhineland, and he strongly urged the wholesale introduction of iodine-containing salt in the diet of the whole community of the Third Reich.

These facts I communicated to the appropriate authorities in Whitehall in the early days of the war, but the Scientific Advisory Committee, to whom the letter was forwarded, did not show any interest. In Oct.-Nov., 1941, I published an extensive article on the "Prevention of Disease," and in July, 1943, one on "Diet and Health," and both dealt with the same problem. Of course the German scientist was silent on the origin of his idea, and whether my own countrymen will adopt the same standard of ethics remains to be seen.—I am, etc.,

Penarth.

W. MITCHELL STEVENS.

Wartime Day Nurseries

SIR,—Miss B. R. Abelson, in her interesting letter on nurseries (Oct. 23, p. 527), seems to be under some misapprehension as to the subject of the meeting held by the London Association of the Medical Women's Federation in June. The discussion was concerned not with nursery schools but with the wartime nurseries for children from 4 weeks to 5 years of age who need to be cared for during the long hours that their mothers are at work. The general opinion of the meeting was that not only were these nurseries detrimental to the health and happiness of the children, owing to the long hours, often unsuitable premises, insufficient and inadequately trained staff, and the grave risk of infection, but they did not, in fact, achieve the purpose for which they were designed—that of releasing woman-power for war work. The proportion of staff (including domestic staff) to children in nurseries catering for from forty to fifty children is about one to four, and owing to the incidence of infectious diseases the number of children attending is for long periods much under the maximum possible. In addition

here is the personnel required for the building, equipment, administration, and inspection of the nurseries. It seems probable that these nurseries have used more man- and woman-power than they have set free for the war effort.

A well-planned nursery school, designed for the use of 3- to 5-year-old children during school hours, which is adequately staffed and visited daily by an experienced health visitor and at frequent intervals by a doctor for routine examination of the children, can form a very useful part of the social services of the country, but this does not meet the needs of whole-time women workers. Even so, it must not be forgotten that there is a great risk of infection in groups of very young children, and that the fatality rate among children who develop zymotic disease at these ages is much greater than that of children of ordinary school age. A wartime nursery to which young babies are brought in the early morning and from which they are fetched by tired mothers in the late evening is a very different proposition, and I would join with Miss Abelson in my admiration of the way in which these mothers are undertaking an almost superhuman task.—I am, etc.,

London, S.W.1.

MARJORIE BACK.

X-ray Diagnosis of Phthisis in Symptomless Adolescents or Young Adults

SIR,—In the present urge for mass radiography of the chest the outstanding problem will evidently be how to deal with the symptomless adolescent or young adult cases which, as a result of x-ray examination, have been labelled as tuberculous. It is important to emphasize that these cases are symptomless. In Dr. Macpherson's paper (July 24, p. 48) we read that "a healthy youth, working and playing hard, with no symptoms, is suddenly singled out from his companions and told that he has evidence of pulmonary tuberculosis"; and, again, that "it is not uncommon that, apart from the radiographs, every finding is normal." Such a youth is naturally averse to undergoing a long period of sanatorium treatment, and Dr. Macpherson's answer to this is to go straight for an artificial pneumothorax. "These symptomless patients," she says, "should be ideal subjects for such treatment," or indeed for any kind of treatment (seeing that they are perfectly healthy), provided they can be persuaded to undergo the particular treatment offered.

The crucial question which has to be answered is: "Can x-ray examination alone prove the existence of a tuberculous focus in its earliest phase in the absence of all clinical signs and symptoms?" We have been told by expert radiologists recently that though a shadow may be definitely diagnosed as tuberculous in origin it is often impossible to say whether it indicates active or merely obsolescent tubercle, and that a shadow seen to-day may be gone a few weeks' later. I maintain that until this question can be definitely settled with general agreement among experts it is not fair to the patient to resort forthwith to an artificial pneumothorax. In my own mind I feel perfectly sure that there are shadows which one observer would straightway label as tuberculous, and active at that, and which another observer would be doubtful about or would even negative.

Dr. Macpherson declares that "it is not necessary to attempt a complete collapse of the lung; a shallow pneumothorax sufficient to control and immobilize the diseased lung partially or completely is what is required." I should be interested to know how Dr. Macpherson can guarantee immobilization of a diseased lung by a shallow pneumothorax. I may, of course, be hopelessly out of date, but in our time it was always taught that complete collapse of the lung was the ideal to aim at, except where, in certain fortunate cases, selective collapse—meaning complete collapse of the diseased portion only—was obtainable. Anyone who has looked at the fluorescent screen in a case of artificial pneumothorax must be aware of the quite extensive movement of the incompletely collapsed lung, even though the pneumothorax could by no means be called a "shallow" one. Dr. Macpherson does not hesitate to advise even a bilateral shallow pneumothorax where both lungs show disease. I should, further, like to know what are the scientific grounds for saying that "a shallow pneumothorax for a slight lesion of the lung is unlikely to give rise to complications." Is there any good evidence that complications are less common in a partial collapse than in complete collapse of the lung?

Dr. Macpherson writes as a worker in the Brompton Hospital Research Department, and she avers that the treatment which she advocates "is the one which has been adopted." Does this mean that the honorary physicians on the staff of the Brompton Hospital are agreed in adopting this treatment in the symptomless adolescent or young adult case diagnosed on x-ray findings alone? One would hardly suppose so, for Dr. Macpherson herself admits, indeed emphasizes, that "as yet it is impossible to assess its value."

If, as stated by her with regard to adolescent pulmonary tuberculosis (Report VII), "the period of time between the first appearance of the lesion in the x-ray film and the first symptom varied between three and five years," why should there be such haste to induce a pneumothorax? Surely the more sensible procedure would be to keep such cases under continued x-ray and clinical observation, so long as no development of the lesion is observed under x rays and the patient continues to be free of all symptoms and clinical signs. If either of these conditions is unfulfilled then collapse of the lung might be undertaken: whether partial or complete the experts must decide. In this way many patients would be saved from an unnecessary pneumothorax. We want to know, also, what proportion of these symptomless cases actually develop active disease, and this, apparently, the Brompton Hospital Research Department is unable to tell us, although the Department has now been at work for 14 years.—I am, etc.,

Southborough,
Tunbridge Wells.

E. WEATHERHEAD.

* When the foregoing letter was standing in type Dr. Weatherhead wrote as follows:

Owing to delay in receiving my copies of the *Journal* my letter was sent in before I had seen the issues published later than Oct. 2, which contain some interesting letters on the question at issue.

Treatment of Lupus Vulgaris

SIR,—I wish to correct a statement I made in my letter (Oct. 9, p. 436) in which I stated that the Royal Infirmary, Edinburgh, was the only voluntary hospital to possess three Finsen-Lomholt lamps. My letter was written before Dr. Arthur Burrows's letter was published, and on communicating with him he informed me that the London Hospital has more. When I was in London early in 1938 I knew that there was a Finsen-Lomholt lamp in each of two hospitals there, and the dermatological friends of whom I made inquiries were not aware of the proposed change-over of apparatus at the London Hospital. I had assumed, wrongly as it turns out, that no considerable number of these lamps had been installed in one hospital in the eighteen months prior to the war.

It is a great pleasure to those of us long connected with the treatment of lupus vulgaris to know that the London Hospital is continuing, with the latest and most efficient apparatus, the fight against lupus for which it has so long and so justly been renowned.—I am, etc.,

Edinburgh

ROBERT AITKEN.

Psychology and the Common Cold

SIR,—Dr. L. Leslie's remarks (Oct. 16, p. 494) on this subject have point. Many psychiatrists would disagree with Dr. E. W. Braithwaite's conclusions as to the invariable relationship between "a particular emotional state," which he leaves unspecified, and the origin of the common cold. It must be remembered among other things that psychoneurotics, from whom Dr. Braithwaite's conclusions are drawn, are very suggestible subjects. Many of their "colds" are not nasopharyngeal infections at all, but are episodes of "nasal neurosis" induced, as Ross pointed out, by auto- and hetero-suggestion.

True colds are often enough accompanied and preceded by emotional states, specific for the sufferer and depending on his temperament and personality structure. Like all other organic illnesses they have, in other words, a psychic aspect of greater or less importance. Such a psychic aspect is certainly likely to be more noticeable in psychoneurotics because of their

general emotional instability, but this does not mean that "the specific factor is psychological; the microbic one secondary."—I am, etc.,

E. HOWARD KITCHING,
Psychiatrist, Manchester Royal Infirmary.

SIR,—I was amazed to read the letter from Dr. E. Wrigley Braithwaite (Oct. 2, p. 433). His letter contains five contentions, all of them high-coloured extravagances and overstatements. He claims twenty-five years' practice of psycho-analysis, but does not mention the number of colds he has observed. His first contention is that in the psychoneurotics under his treatment "a cold invariably occurred in a particular emotional state." Surely the experience of the profession is that the spread of the complaint is due to droplet infection by a virus, and is no more concerned with emotional states than any other infection, be it by virus or bacterium.

The fourth contention is that "cold, wet, hunger, exhaustion, and a source of infection do not result in the development of a cold in the absence of the appropriate emotional state." Now every practitioner knows that emotional states may be predisposing, but to particularize such a state as the *sine qua non* is ludicrous in the extreme. It really seems that such teaching as the above is a wilful retrogression to the aetiology of the Middle Ages.—I am, etc.,

Hove.

W. BRYCE ORME.

SIR,—Dr. E. W. Braithwaite's statement (Oct. 30, p. 559) that "the specific factor is psychological" seems to imply that there is only one essential factor in the determination of a "cold"; but, as Drs. Anderson and Parry point out, microbic and physiological (and, I should add, some nasal pathology) are equally essential. Does he mean anything further than that "in his opinion as a psychologist, the most important [to him] of the many factors determining a cold is the psychological"? He says he would use power, if he had it, for a concentrated attack upon "the national neurosis" (cold proneness). Would he tell us how this could best be carried out? and if the terms of reference and the proceedings could be expressed in medical terms which are clearly understood by the physiologist, pathologist, and bacteriologist?—I am, etc.,

F. A. PICKWORTH.

Birmingham.

SIR,—I believe with Dr. E. Wrigley Braithwaite that infective micro-organisms of any kind, including those of "the common cold," can obtain a mastery of the bodily defences only when the individual is depressed or over-fatigued. A happy person has a remarkable immunity. I also feel that Dr. Parry is on the right lines when he associates nasal catarrh and sex; only my observation goes to show that it is not so much "abuse" of sex but lack of proper use of the sex organs which promotes congestion of the nasal sinuses.

The same processes which lead to anxiety neurosis—namely, stimulation followed by frustration—can, I believe, initiate a chronic nasal catarrh alike in courting couples, women who cheat the uterus by contraceptives or are deprived of orgasm, and habitual masturbators.—I am, etc.,

Birmingham.

R. MACDONALD LADELL.

Atmospheric Pollution with Cement Dust

SIR,—I have read with great interest your annotation (Oct. 16, p. 489) on the smoke nuisance prevailing in all the big cities of Britain. I regret, however, that you made no mention therein of the equally great, if not greater, nuisance caused by cement dust, which pollutes the atmosphere of places where cement is manufactured. I do not happen to know what it is like in other districts, but my experience of this district and others in the Thames Valley is such as to compel me to place on record my sense of the abominable nuisance resulting from such air pollution, to say nothing of the danger it constitutes to the health of those who unhappily have to live in those districts.

The extent to which such pollution occurs is simply unbelievable, through the constant and never-ending clouds of cement dust pouring night and day out of the chimneys about here. Flint dust is used in the manufacture of cement, which constitutes an additional danger. One must live in this district to be able to realize how very justifiable is my complaint.

which I venture to suggest calls for urgent redress, just much as the smoke nuisance does elsewhere. I trust you think it imperative to draw the attention of the authorities to it in one of your forthcoming leaders.—I am, etc.,

Greenhithe.

D. W. STANDLEE

Vincent's Infection during Arsenical Treatment

SIR,—The recent article by Squad. Ldr. E. C. O. Jewest on the misuse of intravenous N.A.B. for Vincent's infection (Sept. 18, p. 360) and the subsequent correspondence, prompted me to report the following case:

The patient, a female aged 19, suffered from syphilis, gonorrhoea. She attended voluntarily on June 29, 1943, a twice-named contact under Regulation 33B. There was a pain chancere on the inner surface of the left labium majus near fourchette and strongly positive Wassermann and Kahn reactions. Treatment was instituted forthwith, and by Sept. 16 she had completed a first course of intravenous stabilarsan (4.65 g.) with current bismuth (2 g.). The patient was advised early in treatment to receive attention for her many carious teeth. This advice ignored, and on completion of the first course there was a bismuth blue-line in the gums.

On Sept. 23, one week after the completed course, the patient reported to the clinic complaining of a sore mouth. There was an infected ulcer around the left third molar in the lower jaw, the throat was clear. Vincent's organisms were present in a smear. The patient was treated with glycothymoline mouthwash and daily local applications of gentian violet. The infection ulceration spread within the next few days to the inner surface of the tongue on both sides and around the right lower molars, the inner surfaces of both cheeks; the throat remained clear. On Sept. 28 another intravenous injection of stabilarsan was given (0.3 g.). In the next two or three days there was no local improvement and a deterioration in the general condition.

On Oct. 2 the local treatment suggested by Squad. Ldr. Jewest was instituted, with the result that within two days ulcers were clean and healing, pain had disappeared, and there was great improvement in the general condition. By Oct. 8 all lesions had healed.

Several cases of Vincent's infection of both throat and gums have been referred to this clinic as suspected cases of second syphilis. These have responded promptly to intravenous stabilarsan; two injections have usually sufficed. I agree with Major Davis (Oct. 9, p. 464) that a possible explanation of failure in those cases which have received previous arsenical therapy may lie in the organisms having become drug-resistant.

It would seem that where a case of Vincent's infection is known to have had previous intravenous arsenic, faith should be put in local treatment. Vincent's infection in patients previously treated with arsenic should at least be tried with intravenous arsenic.—I am, etc.,

V D. Clinic, Rotherham.

R. C. WOFINDEN

Treatment of Chronic Rheumatism

SIR,—In your issue of Oct. 23 (p. 510) G. Laughton So writes: "The literature of intra-articular chemotherapy, for example, hardly exists except for Forestier's scanty note. In the light of this rather sweeping statement it might be interesting to cite the following lines of the second edition of a monograph (L. Schmidt, *Clinical Aspects and Treatment of Articular Rheumatism*, Vienna, 1930):

"The surgical treatment of chronic arthritis, particularly chronic infective arthritis, does not in general receive as much consideration as it should. E. Payr has done well to draw attention in numerous papers to the fact that chronic infective arthritis is not an unbridgeable borderland between medicine and surgery but rather a broad field in which the clinical and therapeutic co-operation of an experienced surgeon and physician may produce striking results. It also applies to the cases in which medical treatment alone can do nothing more. His own special methods of 'continuous anaesthesia' and 'continuous antiseptics' of the joints (through intra-articular injections) have certainly done much to develop these possibilities. In order to make the possibilities of surgical treatment better known to general practitioners and physicians, I quote fully from Payr's scheme of treatment."

Unfortunately it is not possible to reproduce within the framework of a letter the whole quotation, extending several pages of the monograph, but those who are interested would do well to read Payr's genuine work on the subject ("Chronische Infektarthritis und ihre Chirurgische Behandlung").

durch Injektionen," *Z. klin. Med.*, 1928, 108, No. 1-3). In fact, in the course of years many hundreds of cases of chronic rheumatic joints have been successfully treated at my clinic by injecting various substances into the joints according to the requirements of the cases.

I do not know whether anyone, after having studied the above-mentioned works, will be inclined to accept Scott's "claim of innovation," but I hope that everybody will agree that he has made a very valuable further contribution to a since long-practised medico-surgical method, which, he suggests, should be called forthwith—rightly or wrongly—"local chemotherapy in chronic rheumatism."—I am, etc.,

Newark.

L. SCHMIDT, M.D. Prague.

"Opponents of the Medical Profession"

SIR.—My colleagues and I welcome the review of Bulletin No. 1 of the Medical Policy Association (London) in your issue of Oct. 30, and look forward to your comments and criticisms of the contents of subsequent numbers. So far we have issued nine bulletins. We note that no statement of fact in Bulletin 1 has been challenged, and we consider your article a fair analysis of its contents, though doubtless not altogether fair in intention.

The charge of anti-Semitism is now a well-known device in the technique of denigration. In other words, the legitimate reactions of the Jews and their sympathizers are being deliberately exploited as a technical device to achieve certain ends—namely, to discredit one's opponents. It is well that the Jewish community should note this development. We deny that anti-Semitism is implicit in our policy or in the technique with which we implement that policy, and such an assumption is an illegitimate inference from the contents of Bulletin 1. A historian of, say, Christianity would, in discussing origins, find it necessary to record Jewish plots and persecutions. Is he therefore to be labelled an anti-Semite? Bulletin 1 dealt with origins.

May we make one or two further comments? First, it is surely naive to believe that what appears nowadays in the evening paper to which you referred is necessarily true. The definition of Jewish Fascism which you quote in your article is not ours. Secondly, in quoting the book *Protocols of Zion* we were careful to indicate that there are doubts as to its authenticity. Thirdly, with regard to the question of whether there exists an active organization which desires war rather than peace and which, operating behind the obvious economic and political causes of war, directs high policy, our attitude is that there is a case for investigation. Certain evidence exists, and if proved valid the persons involved must be tried, and if guilty punished, else we shall never have an end of wars. It is pertinent to ask oneself, for example, whether there is not some connexion between the planners of to-day and the pacifists and disarmament propagandists of yesterday. Finally, may we again express our pleasure at your decision to review our literature?—I am, etc.,

London, W.1.

A. RUGG-GUNN.

A "Charter of Health"

SIR.—Dr. Norman Sprott's letter (Oct. 23, p. 525) is of great interest to the medical profession of every Allied nation. Therefore, a charter of health should not, I think, be confined to one country alone, but extended for whole continents and indeed for the whole world. The problem of the decline in population has, for instance, the greatest significance for Western and Central Europe; but it is, to-day at least, not a problem for Russia and Asia. A charter of health with a universal meaning can, therefore, only be drafted on international lines. For this very purpose the Anglo-Czechoslovak Founders Committee (Health Charter), 18, Grosvenor Place, S.W.1, has instituted in the course of the year an "open competition" for the drafting of an Inter-Allied Charter of Health which implicates the suggested "Atlantic Charter of Health."

In the light of the recommendations made by Dr. Sprott and upon an international basis I wish to draw attention to the competition now running. Particulars can be obtained at the above address.—I am, etc.,

London, W.C.1.

JUL Löwy.

Obituary

F. JOHN POYNTON, M.D., F.R.C.P.

We regret to announce, the death of Dr. F. J. Poynton, consulting physician to University College Hospital and to the Hospital for Sick Children, Great Ormond Street, who had been living at Combe Park, Bath, since his retirement from active practice in London. He died on Oct. 29.

Frederic John Poynton, son of the Rev. F. J. Poynton, rector of Kelston, Bath, was born in 1869, and, like his elder brother A. B. Poynton, D.Lit., formerly Master of University College, Oxford, was educated at Marlborough College. He began his medical studies at University College, Bristol, and continued them in London at St. Mary's Hospital, where he won a scholarship in anatomy and physiology. He qualified M.R.C.S. and L.R.C.P. in 1893, and in the following year gained first-class honours at the Final M.B. Lond. examination; he took the M.D. in 1896, the M.R.C.P. in 1897, and was elected F.R.C.P. in 1903. Poynton became physician to out-patients at the Hospital for Sick Children in 1900, physician in 1919, and consulting physician in 1934. His connexion with University College Hospital began in 1903 as assistant physician; he was promoted to the full staff in 1910, and on retirement in 1934 was made consulting physician. He wrote in 1907 a small book on *Heart Disease and Thoracic Aneurysm*, and had for some years before then worked with Alexander Paine in an investigation of the cause and nature of juvenile rheumatism, which they recorded in 1913 in *Researches on Rheumatism*. It was in 1900 that Poynton and Paine obtained from the blood and inflammatory lesions in cases of rheumatic fever a diplostreptococcus and began to formulate the streptococcal hypothesis of the causation of acute rheumatism. This view, upheld tenaciously against all comers, was by no means the only contribution Poynton made to the study of rheumatism in childhood, and his work in that field and in paediatrics generally was recognized in 1930 by the award of the Dawson Williams Prize, founded in memory of the late editor of the *British Medical Journal*. Jointly with Dr. Bernard Schlesinger he published a book on *Recent Advances in the Study of Rheumatism*, which reached a second edition in 1937. Many years earlier he had edited the fifth and sixth editions of *Artificial Feeding of Infants* by W. B. Cheadle, whose pupil he had been both at St. Mary's and at Great Ormond Street, and before then he had published with G. F. Still a paper showing that the most severe effects of the rheumatic poisons in a subcutaneous nodule were tiny areas of necrosis, thus confirming Scandinavian investigators. His long service in the cause of sick children was recognized by election as president of the British Paediatric Association.

Poynton joined the B.M.A. in 1898, was secretary of the Section of Medicine in 1907, vice-president of the Section of Diseases of Children at the Centenary Meeting in 1932, and president of the Section of Paediatrics in 1934; he was also an active member of the special subcommittee set up by the Council in 1923 to inquire into the question of cardiac diseases in children. At the Royal College of Physicians he gave the Bradshaw Lecture in 1924 on the prevention of acute rheumatism, and was Senior Censor in 1930; he was also Lettsomian Lecturer in 1927 before the Medical Society of London, Long Fox Lecturer at Bristol in 1934, and Harben Lecturer in 1936. The Cardiac Society made him an honorary member.

Poynton was devoted to his native county. He had been a fine cricketer in his younger years and played for Somerset from 1891 to 1896; he also played hockey for Middlesex. Field sports were not his only recreation; he was a music lover and a Fellow of the Philharmonic Society, and something of an archaeologist.

R. H. writes:

By the death of Dr. F. J. Poynton the diminishing band of elder paediatricists has suffered another loss, for, although he was also a general physician and for many years on the staff of University College Hospital, it was as a children's specialist that he was best known. His chief original work, as everyone knows, was on the bacteriology of acute

rheumatism, in which he was really a pioneer, and, although his conclusions have never been fully confirmed, rheumatism in its different manifestations remained his dominant interest throughout life, and the destruction of his original specimens in the recent damage to the Museum of the Royal College of Surgeons was a great grief to him. He was a devoted servant of the Hospital for Sick Children, Great Ormond Street, where he served his full time on the staff, and its welfare was always very dear to him. An assiduous teacher, first in the out-patient department and afterwards in the wards, many of his pupils thought him rather cynical and sarcastic, but all who got to know him well realized that these were only superficial mannerisms which concealed a real kindness and warmth of heart and a generous love of children. He was an original member of the British Paediatric Association and its president in 1932, and he thoroughly enjoyed its annual meetings, at which he was able to show the more genial side of his nature and to make friends with his junior colleagues.

Poynton had private sorrows and disappointments which would have embittered most men, but he bore them and the enforced tedium of his later years with a manly dignity and philosophy. He has gone home after a hard-working and high-principled life; but he was not a happy man and quite out of sympathy with the trend of public and professional life to-day, and his staunch individualism would have agreed ill with the shape of things to come. For his own sake, therefore, one is glad that he is at peace.

C. J. MACALISTER, M.D., F.R.C.P.

Although it is sixteen years since Dr. C. J. Macalister retired from active practice and went to live in Gloucestershire far from his native Merseyside the news of his death, which took place on Oct. 25, will evoke many vivid memories of him, as well as widespread regret, in Liverpool and in large circles of the medical profession elsewhere. He practised in Liverpool for over forty years, and, apart from his skill as a physician, he made his mark on the city, especially for his pioneer work in child welfare and in many social causes.

Charles John Macalister was born at Bootle the third son of William Boyd Macalister, a man closely connected with the shipping industries of the Mersey. He was educated at Liverpool High School and the University of Edinburgh, graduating in medicine in 1884. He returned to Edinburgh eleven years later to receive his M.D., with commendation, and in 1909 he was elected a Fellow of the Royal College of Physicians of London. After qualification he returned to Liverpool as junior resident surgeon at the Children's Infirmary, and from 1885 to 1887 he held a similar resident post at Manchester Children's Hospital. In 1887 he became pathologist at the Royal Southern Hospital, Liverpool, the hospital in which, as a member of its medical staff for 25 years, some of his best work was done. Settling down in practice in Liverpool he devoted himself particularly to work among children. One of his first enterprises was an out-patient clinic in connexion with the Liverpool Medical Mission. This introduced him into the homes of the poor and gave him an understanding and compassion, especially for the children of the slums, which never left him. In 1892 he was appointed physician at the Stanley Hospital, Liverpool, a post he held for eight years, and for fifteen years he was physician to the Liverpool Home for Incurables. It was while holding this latter position that it was brought home to him strongly that many of the children afflicted with crippling diseases, such as surgical tuberculosis, only needed regular treatment and open-air life to be restored. Sir Robert Jones, who for many later years was surgeon to the Royal Southern while Macalister was physician, was also greatly interested in these children, and the help of some generous friends was enlisted. A ward of twenty beds was placed at their disposal at West Kirby Convalescent Home by Mr. (afterwards Sir) Alfred Paton, and this became an independent unit known as the Liverpool Country Hospital for Children. Afterwards came the transfer to Heswall, amalgamation with the Liverpool Infirmary for Children, and the change of name to the Royal Liverpool Children's Hospital as at present. It is now, with its three branches, an institution of four hundred beds. It may be said to owe its origin to Macalister's vision and energy forty-five years ago—ten years before even the Treflar Homes at Afton

were founded. Of both the Royal Liverpool Hospital for Children and the Royal Southern (now incorporated in the Royal Liverpool United Hospital) he was made consulting physician on his retirement. He was also formerly honorary physician to the Leasowe Hospital for Children and to the Liverpool Schools for the Deaf and Dumb and the Adult Deaf and Dumb Benevolent Institution.

As lecturer on clinical medicine at the University of Liverpool he had an influence on several generations of undergraduates. He had been president of the Liverpool Medical Institution and the Biological Society, and was a frequent contributor to the medical journals. In the B.M.A., which he joined in 1888, he was vice-president of the Section of Diseases of Children, including Orthopaedics, when the Association met in Liverpool in 1912. From its inception he had been associated with the Liverpool Scottish Territorial Regiment, and during the war of 1914-18 he remained with it as surgeon major, and carried out a great deal of inspection and other work in the Western Command. He was physician-in-charge of the Arrow Hall and Croxteth Hall Military Hospitals.

On his retirement in 1927, at his beautiful home at Bourton-on-Water, Gloucestershire, Dr. Macalister devoted himself to writing *Liverpool hospital history from a personal point of view*. In 1930 he brought out a history of the Royal Liverpool Country Hospital for Children, and this was followed in 1936 by a volume narrating the origin and history of the Royal Southern Hospital. Earlier writings of his concerned the history of ambulance in warfare, child welfare and its organization, and the education of deaf-mutes.

Dr. DAVID ST. HELLIER HORGAN, who died in Lisbon on Sept. 10, was born at Cork in November, 1884. He was educated at Clongowes Wood College and at Queen's College, Cork. After qualifying M.B., B.Ch.(N.U.I.) in 1909 he joined the R.N., being stationed at Crete during the greater part of his two years' service. Wishing to specialize in ophthalmology, he left the Service in 1911 and, after acting for one year as house-surgeon at the Oxford Eye Hospital, obtained the D.O.(Oxon). He then obtained the position of ophthalmic surgeon to the Egyptian Government. Finding the work in Egypt uncongenial he resigned that position early in 1914, returning to his native town, where he carried on a very successful practice as an ophthalmic surgeon. Since 1922, when he retired from practice, Dr. Horgan lived in Lisbon, where he was a well-known and respected member of the British community, and at his lovely home at Cintra a warm welcome was always extended to passing British and Irish friends.

Dr. KINGSLEY WASSELL LEWIS of Pontypridd, Glamorgan, died suddenly on Sept. 14. The eldest son of the late Dr. B. M. Lewis, he was born at Pontypridd in 1890; he was educated at Mill Hill School, University College, Cardiff, and University College Hospital, London, where he won the Fellows Gold Medal. Almost immediately after qualifying M.R.C.S., L.R.C.P. in 1914 he joined the R.A.M.C.S.R., and served for a year in France and for two years at Salonika, where he attained the rank of major. On returning to England he held the posts of house-physician and house-surgeon at U.C.H., and graduated M.B., B.S.Lond. in 1921. Dr. Lewis was for a long period surgeon to the Pontypridd and District Hospital. He joined the B.M.A. in 1919 and was chairman of the North Glamorgan and Brecknock Division in 1936-7. A correspondent writes: Many tragedies have befallen the mining districts of South Wales in recent years, but it is doubtful if any has suffered more by the death of one man than has befallen the town and district of Pontypridd by the tragic death of Kingsley W. Lewis. In 1915 he went abroad as second in command of a motor ambulance convoy. Later he was appointed M.O. of the 11th Battalion the Welch Regiment, with whom he served on the Somme. Subsequently he became registrar to the 29th General Hospital at Salonika and was invalided home in 1918. After a period in hospital he was attached to a military hospital in Colchester, and in 1919 he joined his father in general practice at Pontypridd and very soon became a very familiar and greatly loved personality in the town of his birth. It is felt by his friends and patients that he worked himself, in the early 'twenties, almost to a standstill, with the result that his constitution became undermined and he was unable to stand the strain placed upon him by the abnormal amount of work which he was called upon to do in this war. Dr. Kingsley Lewis had to struggle single-handed with a large practice in a district in which the population was substantially increased by the arrival of evacuees, and

many others. No one ever heard him complain of the extra work, his time and skill were still at the disposal of his patients, his own pleasures and time for recreation and rest were resolutely put on one side, and his friends saw less of him than ever before. Ever since the outbreak of the war he had served in the Local Medical War Committee of the North Glamorgan and Brecon Division of the British Medical Association.

Dr. HAROLD HENRY STIFF died on Sept. 16, aged 70. He had lived at Winchester for some years past, but spent the greater part of his professional career in general practice at Bury St. Edmunds, where he was honorary surgeon to the West Suffolk Hospital. From Dulwich College he went up to Caius College, Cambridge, in 1892, and then to St. George's Hospital, where after graduating M.B., B.Ch. in 1902 he served as house-physician; he also held the post of house-surgeon at the West London Hospital. Dr. Stiff was for two years in the British Expeditionary Force with a temporary commission in the R.A.M.C. He had joined the B.M.A. in 1903, was chairman of the West Suffolk Division in 1922-3, and represented that Division at the Portsmouth Annual Meeting in July, 1923. A correspondent writes: Dr. Harold H. Stiff, who has died at Winchester in his seventieth year, was well known in Suffolk through his many years of practice in Bury St. Edmunds, especially as surgeon, and in due time consulting surgeon, to the West Suffolk General Hospital there. He was educated at Cambridge University and St. George's Hospital, where he filled all the resident posts with great credit to himself. Dr. Stiff was an all-round general practitioner of quite unusual attainments; and as he had also a conciliatory address, a kind heart, and tact in his dealings with patients, it is not surprising that he attained very marked success in Bury St. Edmunds and carried with him in his retirement the good wishes of a very wide section of that part of East Anglia where he had been in harness ever since he finished his London resident appointments.

The death of JOHN OVEREND PRIESTLEY on Sept. 21 at the early age of 44 removes one whom the gods may well have loved but with whom the fates dealt in tragic manner. A correspondent writes: Leaving Charterhouse no more than a plucky boy he was flying in the R.A.F. over enemy lines by the time he was 18, and down in flames on the wrong side of those lines not much later. With the war over he entered the Middlesex Hospital Medical School and qualified in the minimum possible time, gaining the Hetley prize in clinical medicine. As house-physician to Dr. Voelcker he profited from the extraordinary powers of observation of that master and quickly exhibited a flair for diagnosis. Seeing these possibilities widen every day he took up radiology, obtained the D.M.R.E., and went back to the R.A.F. as medical officer. He was the first man in this branch of the Services with any special qualification in x-ray matters, and in a short time the result of his knowledge was an improvement both in methods of radiological examination and in x-ray technique. He was in his *métier*, he liked Service life, and he was able to feel that he could contribute to the advancement of at least one branch of medicine; then fate stepped in and dealt him a blow from which he never really recovered: he had developed phthisis. Priestley put himself in the hands of a sanatorium chief whose creed and practice were to get his patients back to work at the earliest possible moment. So within 6 months the patient started to build himself a practice in the country. He built up three practices over a period of 15 years with frequent rests for recuperation. But he never really got on his feet; he played a losing game with pluck and determination, yet seeing the years slip by, with himself not quite so well each year. "Jack" Priestley was exceptionally endowed: his quick eye and sensitive hand served him in the air, by the bedside, and alongside the rivers in Ireland where many an hour was spent. At heart he was a countryman, and those especially who knew him from boyhood grieve as they wonder how it was that a benevolent fate so seldom appeared in shaping his destiny.

We regret to announce the death of an old friend of this Journal, Dr. F. WILLIAM COCK, who after retiring from practice in London devoted himself to his hobby, antiquarian research, and was recognized as one of the best authorities on the archaeology of the county of Kent. Frederick William Cock, son of Frederick Cock, M.D., was born in London in 1858 and studied medicine at University College, London, and at Newcastle, graduating M.B. and M.S. of the University of Durham, with highest honours, in 1884 and M.D. in 1886. Having worked as senior resident at the Newcastle-upon-Tyne Infirmary Dr. Cock returned to London and became well known as a skillful part-time anaesthetist. For 15 years he held the post of anaesthetist to the Dental School of Guy's Hospital, and during the last war was appointed honorary anaesthetist to the King George Hospital. He joined the B.M.A. in 1889

and was an active member of the Harveian Society of London, holding office as president in 1906. For 46 years he had been a liveryman of the Society of Apothecaries. He was a Fellow of the Society of Antiquaries, a member of the council of the Kent Archaeological Society, and a J.P. for Kent. His ancestors had long been established in the neighbourhood of Romney Marsh, and it was natural that William Cock, with antiquarian tastes and love of local history, should settle in retirement at Appledore, Kent, to live among his books and old associations. His Kent library is one of the most complete and famous in the county. From time to time he wrote learned little notes on out-of-the-way subjects for these columns, and was always happy to answer questions coming within his range of expert knowledge.

The death of Mr. GEORGE MORGAN on Sept. 23 in a nursing home at Hove removes a veteran member of the B.M.A. who was for many years a leading figure in the medical profession of Brighton. Born at Market Drayton, Salop, in 1860, he was educated at Market Drayton and Auden Grammar Schools and came to London as a student of Charing Cross Hospital. He took the L.S.A. in 1883 and the M.R.C.S. and L.R.C.P. in the following year, and obtained the F.R.C.S.Ed. in 1895. At Charing Cross he won a senior scholarship and gold medal. He went to Brighton in 1885 as house-surgeon to the Royal Alexandra Hospital for Children, and after holding other house posts he was elected assistant surgeon in 1890, surgeon in 1895, and consulting surgeon in 1919. During the last war he held a commission as captain in the R.A.M.C. Mr. George Morgan joined the B.M.A. directly he gained his first appointment, and was always an enthusiastic believer in its usefulness to medical men, especially the younger generation. At the Brighton Annual Meeting in 1913 he held office as vice-president of the Section of Bacteriology and Pathology; he was president of the Sussex Branch in 1922-3, and chairman of the Brighton Division for two periods. At the age of 74 he wrote: "I believe in work, and am as fond of it as I was at 24. My chief hobby is the study of fungi, and as a member of the Mycological Society I attend all forays and lab. demonstrations." This hobby brought him into active membership of the Brighton and Sussex Natural History Society, of which he became vice-president.

Mr. GEORGE HEBB COWEN, consulting surgeon to the Royal South Hants and Southampton Hospital, died in a nursing home at Sarisbury, Hants, on Sept. 25, aged 71. A student of the London Hospital, he qualified in 1893 after winning an exhibition and gold medal in materia medica and pharmaceutical chemistry at the Intermediate London M.B. examination. He graduated M.B. (with honours in medicine and obstetric medicine) and B.S. (with honours in surgery) in 1894, proceeded to the M.S. in 1896, and took the F.R.C.S. a year later. His first appointment to the Royal South Hants and Southampton Hospital was in 1899 as assistant physician, but he changed to the surgical side of the visiting staff and also became consulting surgeon to the Southampton Borough Hospital and to the Romsey and District Hospital. Mr. Cowen joined the B.M.A. in 1902, and was president of the Southampton Branch in 1915. He was also an active member of the Southampton Medical Society until his retirement from practice in 1937, when he received a presentation from nearly one hundred doctors in the neighbourhood. Sixty colleagues attended the ceremony presided over by Sir Russell Bencraft, and speeches were made testifying to Mr. Cowen's great work in the town. Thenceforward he lived at Newbury, Berks.

Dr. HENRY BEDINGFIELD, formerly of Leeds, died at Rugby on Sept. 28. He was born on Dec. 10, 1889, and studied medicine at the University of Edinburgh and at University College Hospital, London. He graduated M.B., Ch.B.Ed., with honours, in 1911 and gained highest honours for his M.D. thesis in 1928. He took the M.R.C.P.Lond. in 1926. After qualification Dr. Bedingfield held house appointments at the Queen's Hospital for Children, Hackney Road, at the Hackney Infirmary, and at the City of London Chest Hospital. In 1913 he entered the R.A.M.C. and was on active service in 1914-19, winning the D.S.O. and retiring with the rank of major. While in practice at Leeds he published papers on viscerotoposis and nervous dyspepsia in the *Quarterly Journal of Medicine* and the *Proceedings of the Royal Society of Medicine*. He joined the B.M.A. in 1917 and was honorary secretary of the Leeds Division from 1931 to 1941.

We have to announce the death on Sept. 29 of Mr. WILLIAM JOHN HARRISON, senior honorary surgeon to the Newcastle-upon-Tyne Throat, Nose, and Ear Hospital and aural surgeon to the Ministry of Pensions Hospital at Newcastle. He studied medicine at the Durham University College of Medicine and at St. Thomas's Hospital, London, graduating M.B., B.S. in 1899 and taking the English Conjoint diplomas in 1902.

OBITUARY

Before settling in practice as an oto-rhinologist in Newcastle he held a house post at the London Temperance Hospital and travelled widely as a ship surgeon. During the last war he reached the rank of major in the R.A.M.C.(T.A.), was mentioned in dispatches and wounded in 1915; he received the Territorial Decoration in 1925. Mr. Harrison was consultant in his specialty at the Ingham Infirmary and had charge of the ear, nose, and throat department of the Fleming Memorial Hospital for Sick Children. He had served on the Council of the Laryngological Section of the Otolological Society; he was also a past-president of the Newcastle-upon-Tyne and Northern Counties Medical Society. He joined the B.M.A. in 1909, and published a number of papers on otitis media and mastoid disease.

RAYNER DERRY BATTEN, who died on Oct. 22, was born at Plymouth in 1858, the son of John Winterbotham Batten, Q.C., and elder brother of F. E. Batten, the neurologist, and of J. D. Batten, artist and illustrator. He studied medicine at St. Bartholomew's and in Germany, and took his M.D. London in 1886. He was H.S. at Bart's and R.M.O. at the Brompton and at Addenbrooke's, but at the same time did ophthalmic work at Moorfields, where he became assistant surgeon, and in the end gave up general practice for 33 years, remaining on at the Western Ophthalmic Hospital until 1913 and was the Medical and Management Committees until 1913 and his death. He was a member of the B.M.A. until 1913 and was hon. secretary of the Section of Ophthalmological Society and became vice-president of the Oxford Ophthalmological Society. He was exceedingly happy in his family life, and of his four children two, a son and a daughter, followed him into the medical profession, while another daughter has worked for many years in the "welfare of the blind" department of the L.C.C. A colleague writes: Rayner Batten was essentially a clinician. Though slow to make up his mind he had the true clinical instinct, compounded of painstaking observation, wide experience, and a retentive memory. The years spent in later years gave to his early work (e.g., a paper on the genesis of myopia) a background which may have faded somewhat in later years but was never entirely obliterated. Twenty years ago Batten suggested that the technique of ophthalmic surgery was not for the many but for the few, and should be shared between ophthalmic physicians and ophthalmic surgeons. Something akin to this is now again under discussion. Batten's own operative skill was considerable. He had a light, sure touch, devoid of tremor, which endured until advancing deafness compelled his retirement. He attached great importance to "good hands" in all who did ophthalmic work. His life-long hobby was wood-carving, and possibly the "feel" of tools thus acquired inspired the design of some of his instruments, originally fork is still of value, and a hydrophthalmoscope, a forerunner of the contact lens—is often used in the treatment of purulent conjunctivitis by hypertonic solutions. One of his last tasks, undertaken with the assistance of his artist-brother, was painting of fundus artists. The first group of artists was trained at the Western Ophthalmic Hospital under his supervision, and from these a school, which still continues to do excellent work, developed and was later, for a time, under the direction of Mr. Head. This was the source of all the present fundus-painting facilities.

RICHARD AUSTIN FREEMAN, M.R.C.S., L.S.A., who died at Gravesend recently at the age of 81, was one of those medical men who have forsaken medicine for literature—Somerset Maugham, Brett Young, Warwick Deeping are other contemporary instances. Like another doctor, Conan Doyle, he made his name by his detective fiction, an art in which very many have dabbled since Doyle's time, but in few cases with the success which attended Freeman. He was born in 1862, educated privately and at Middlesex Hospital, where he was H.P. after qualifying in 1886. Thence he went into the Gold Coast Medical Service, served in the Ashanti expedition of 1889, and was invalided out in 1891. For a time he was in general practice, but after five years of it went back into salaried employment, first in the Prison Medical Service and then under the Port of London. He served in home units during the 1914-18 war, and later became a Freeman of the Apothecaries Society. His first adventure in literature was as far back as 1898, when he published an account of Ashanti; but he soon found his *métier* as a writer of crime detection, and for nearly forty years had poured out a steady stream of well-written and popular fiction of this type. His methods were rather nearer to those of Conan

Universities and Colleges

UNIVERSITY OF LONDON

The Faculty of Medicine has elected Mr. John B. Hunter, M.Ch., F.R.C.S., to be its Dean from Oct. 1, 1943, for the remainder of the period 1942-4, in place of Sir Girling Ball, F.R.C.S., resigned.

UNIVERSITY OF LEEDS

Endowment of Prize in Anatomy
A year or two ago Major George Waddington of Collingham and Mr. Guy Waddington of Halifax decided to leave their bodies to the Anatomy Department of the Medical School. In each case the desire was to give aid to medical education, and their wishes were in due course carried out. Recently a group of relatives and friends of these two gentlemen, including Major Waddington's mother, presented to the University a sum of money to found a prize in anatomy in their memory. This prize, to be known as "The Waddington Prize," will take the form of books presented to the most promising student in the junior anatomy class at the Medical School. Mrs. Waddington, in handing over the cheque to the Professor of Anatomy, expressed the hope that the example of her son and her nephew might be followed by others; and in accepting the cheque on behalf of the University the Professor of Anatomy hoped that when others came forward to offer their posthumous services to medicine they might well consider combining the corporeal donation with some form of financial aid to the Medical School, as had been done by the Waddington family.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The annual meeting of Fellows and Members will be held at the College in Lincoln's Inn Fields on Thursday, Nov. 18, at 2.30 p.m., when a report from the Council will be laid before the meeting. Fellows and Members can obtain copies of the report on application to the Secretary, and the agenda paper for the meeting will be issued on or after Nov. 13 to those applying for it.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a quarterly meeting of the Council held on Oct. 23 in the College House, with the President, Sir William Fletcher Shaw, in the chair, Prof. J. J. Kearney was elected to the Membership of the College.
The following were admitted to the Membership: J. K. Baker, J. Kruger, and Katharine I. Liebert.
It was announced that the donor of 1,000 guineas to commemorate the presidency of Sir William Fletcher Shaw wished the

terest to endow a lecture every second year to be given alternately by a member of the College on the subject of infertility and (2) a gynaecologist from the U.S.A. as an expression of the friendship existing between the two nations. At the end of the meeting, of Dr. Douglas Manchester, assumed the office of Vice-President and Mr. Eardley Holland, London, assumed the office of President. A vote of appreciation for the services of Sir William Fletcher was during the past five years as President and during the whole period since the inception of the College was adopted by the Council. The following have satisfied the examiners and have been awarded the Diploma of the College:

Agnes U. Campbell, W. H. Carlisle, J. T. Carroll, J. McD. Corston, Margaret S. Crockett, R. W. Danziger, Grace T. Dawson, Mary E. Eegerton, Charlotte L. Hess, P. G. Lewis, Ellen C. Miller, Mary L. Neville, Mary P. Bort, J. W. H. Simpson, Esther M. Swinnerton, I. W. Totten, A. H. C. Walker.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting of the Faculty the following officers were elected for the ensuing year: *President*, Mr. James H. MacDonald; *Visitor*, Mr. William A. Sewell; *Honorary Treasurer*, Mr. William A. Richard; *Honorary Librarian*, Dr. W. R. Snodgrass; *Representative on the General Medical Council*, Mr. Andrew Allison.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examination, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., and L.R.F.P.&S.Glasg.:

A. C. Austun, F. St. M. Brett, E. D. Cameron, Margaret R. Connolly, M. C. Fitch, E. Frischler, E. Glick, Elizabeth G. Hood, J. G. Leyack, I. M. Lourie, R. Marsi, J. W. Muggoch, D. J. P. Naismith, Elizabeth R. B. Pollard, T. Richardson, Frances Selesnick, A. M. Shokry, H. M. Steel, A. D. Willox.

The following graduates of recognized foreign universities were also admitted licentiates:

K. Friedmann, M.D. Vienna; G. W. Green, M.D. Brussels; Ruth Meier-Blaauw, M.D. Breslau; G. M. Weiss, M.D. Bologna.

The Services

Temp. Surg. Lieut. R. R. Dickson, R.N.V.R., has been mentioned in despatches for constant and untiring devotion to duty and great skill in tending the wounded survivors from a torpedoed merchantman.

Temp. Surg. Lieut. I. S. Jacklin, R.N.V.R., has been posthumously mentioned in despatches for gallantry in organizing the survivors from a torpedoed merchant ship and in swimming from raft to raft, in waters where sharks were known to be present, in order to tend the injured.

Capt. I. Joseph, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Sicily.

CASUALTIES IN THE MEDICAL SERVICES

Wounded.—Capt. F. M. Steel, War Subs. Capt. E. M. Leyland and J. R. Tocher, R.A.M.C.

Prisoner of war.—Temp. Major K. C. Hutchin, R.A.M.C.

Reported missing at sea.—Lieut. R. A. Palmer, R.A.M.C.

Missing on active service.—Surg. Lieut.-Cmdr. S. L. Lord, R.N.V.R.

Missing at sea.—Capt. R. M. Sharpe, R.A.M.C.

Died on active service.—Major K. C. Eden, R.A.M.C.; Fl. Lieut. W. S. Pitt-Payne, R.A.F.V.R.

Died.—Col. W. B. Rennie, M.C., War Subs. Capt. A. E. Locke, R.A.M.C.

REPRIATED MEDICAL OFFICERS

Major-Gen. G. A. D. Harvey, C.B., C.M.G., late R.A.M.C.; Lieut.-Cols. I. A. S. Samuel, M.C., F. J. Morris, M.C.; Majors J. Burns, J. H. T. Challis, W. N. S. Donaldson, G. C. Steel, E. R. C. Walker, W. E. Tucker, J. A. Chapel, R. L. Mackay, M.C., C. H. Imrie; Capt. A. D. Aveling, E. R. Dansie, P. A. Forsyth, R. W. Gunderson, I. Jacobson, J. D. Recordon, G. E. Stoker, N. D. Allan, T. K. Elliott, G. S. Trower, W. C. Harris, M. A. Egan, E. M. Fraser, R.A.M.C.

DEATHS IN THE SERVICES

News has been received of the sudden death in Persia from acute nephritis of Capt. J. H. B. Round, M.A., M.B., B.Ch., R.A.M.C., aged 30. He was the only son of Mr. and Mrs. Harold Round of Edgbaston, Birmingham. He studied medicine at Pembroke College, Cambridge, and the Westminster Hospital Medical School, to which he won an entrance scholarship. While at Cambridge he was secretary to the Cambridge Medical Society. After graduating he served as house-physician at Westminster Hospital and then returned to Birmingham as the first medical officer to the Castle Bromwich Aero Factory and organized their medical services. Subsequently he was appointed as the first medical officer of the Midland Group of the Nuffield Factories, and held this position until he joined the R.A.M.C. in August, 1941. Dr. Round was one of the modern pioneers in industrial medicine, and had made valuable contributions to its present conception.

Col. Sidney Martin Hattersley, M.C., late R.A.M.C., who died on active service from illness on March 24, had a distinguished military career lasting 30 years. He studied medicine at Cambridge University and St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1912. He took the M.B., B.Ch. degrees at Cambridge in 1916, the D.P.H. in 1925, and proceeded M.D. in 1931. After qualification he served as house-physician at Manchester Royal Infirmary. As a junior officer in the R.A.M.C. he was taken prisoner in September, 1916, while serving overseas, and in October, 1919, was awarded the Croix de Guerre, having already won the Military Cross. He was promoted to the rank of colonel in September, 1938, and for his services during the present war was mentioned in despatches at the end of 1941. He joined the B.M.A. in 1912.

Medical Notes in Parliament

Food Values and Farming Methods

In the House of Lords on Oct. 26 Lord Teviot called attention to food values in relation to agricultural methods in view of their importance to the health of man, animal, and plant. No one, he said, who was connected with agriculture could be other than perturbed at the number of diseases among our farm stocks, while the diseases among crops were legion. The object behind his motion was to see that we put planning for the health of our people, animals, plants, and crops first. While the spirit of our people was magnificent and their courage undaunted, their bodily conditions were bad. A report from the B.M.A. summed up the whole situation in this way: "While hundreds of millions are expended in trying to cure, only one-fifth of 1% of the national expenditure and waste through ill-health goes on research to find out, not how to cure but how to prevent." He was entirely in agreement with a balanced diet, but unless the components came from a healthy soil rich in humus, there would be a deficiency of life-giving, disease-resisting properties. We had a sort of cycle—a healthy soil, a healthy plant, a healthy animal, and then a healthy man—and it was the integrity of that life-circle which was so important. We must plan to put back into the soil those things which we took from it. A council of nutrition was suggested some time ago. He hoped it would be set up and that it would take into serious consideration not what we should all eat but whence it came and how it was cultivated. He begged for a Royal Commission or a committee of inquiry in order to combat the present tragic state of affairs.

Destruction of Fertility

The EARL OF PORTSMOUTH said very few doctors would advise their patients continuously to use strong antiseptic nasal sprays; if they did the living membranes would suffer and have no power left of resistance to disease. We were doing exactly that to the soil. With lethal sprays we were destroying the soil's power of resistance, and at the same time were giving continuous doses of chemical food and chemical stimulants so that the infinite complex of bacterial life in the soil was being upset. We were upsetting the vitamin content—that was, the capacity of the soil to produce food—by destroying the humus within the soil itself.

Lord Geddes pointed out that in Prince Edward Island there was a very high standard of health, an extraordinarily vigorous active population, and, quite remarkably, after 50 years of close examination no fall whatever in the birth rate. The population there drew their fresh food from the sea and from the field in the traditional manner, living on simple food-stuffs and the products of their own farms and fishing.

Northern Rhodesia, which had been depopulated by disease, was not an easy country to get people of another race into, and to keep them there in a good state of health. They had given the people food grown on rich humus soil with plenty of life in it. In the result they had beaten back disease and turned that part of Northern Rhodesia into what was a health resort. The positive health of these people was based on food. He supported Lord Teviot's plea for some work to be done in this country to follow up the work now being done in Canada.

Viscount Bledisloe pressed strongly on the Government that the time had come when there ought to be research: research not merely conducted in watertight compartments—the health of plants, the health of animals, and the health of human beings—but comparative research on the important problem of the interrelation between the morbid conditions of soil, plants, animals, and human beings. Very valuable research was being done to-day in New Zealand on diseases of animals and fish. What the doctors did not know, however, was the relation, if any, between the deficiencies in the animals and several mysterious morbid conditions of the human population of

New Zealand. Everywhere doctors were very anxious that research should be instituted into the subject. After a recent debate in the House of Lords he asked some agricultural experts whether phosphate deficiency of pastures was transmitted to the milk of cows fed on those pastures, and if so what effect it had on human beings. There was, however, no knowledge in this country on that subject to-day.

Effect of Fertilizers

The DUKE OF NORFOLK, replying to the debate, deprecated any suggestion of antagonism between chemical fertilizers and humus. There was no evidence whatever, from farming or medical experience, or from the scientists, that the proper and balanced use of fertilizers had any harmful effect on the soil, on the health of crops, or on men. Sir Daniel Hall had said that disease was not a product of modern high farming with chemicals, though it might be the mark of their use in an ignorant manner. So far as this country was concerned our safeguard lay, as ever, in the sound principles of mixed farming. The Ministry of Health was not aware of any medical evidence in support of the view that food produced from soil which had been fertilized by artificial manures was in some cases dangerous to health. The value of a certain amount of humus was beyond all argument, and he thought it might be a mistake if this question were raised to so high a level as the realm of political controversy. He would bring Lord Teviot's request for an inquiry or a Royal Commission to the notice of the Minister of Agriculture and the Ministries of Health and of Food.

Regulation 33B

Dr. SUMMERSKILL asked whether the Minister of Health was satisfied that Regulation 33B had any appreciable effect in reducing the incidence of venereal disease in view of the fact that it had only been brought into operation against 110 individuals. Mr. BROWN said that in his opinion the regulation was effecting its purpose and would increasingly assist medical officers of health in getting into touch with infected persons and inducing them to undertake voluntary treatment. The 110 persons referred to were cases reported more than once up to June 30 last as alleged sources of infection. In addition about 1,780 other cases were the subject of report, but of one report only. Answering a further question, Mr. Brown said he was not going to introduce compulsory notification at the moment. That would require other drastic measures to make it effective. Otherwise the disease might be driven underground. Dr. SUMMERSKILL gave notice that she would raise the question on another occasion.

Yellow Fever Research in Africa

Co-ordination of research on yellow fever in Africa is centred in the Yellow Fever Research Institute at Entebbe, Uganda, which is a unit of the International Health Division of the Rockefeller Foundation. The staff of the institute has carried out immunity test surveys of groups of persons in Uganda, Northern Rhodesia, Kenya, Tanganyika Territory, the Sudan, the Belgian Congo, Somalia, and Eritrea, and the results have been circulated to the Governments concerned. Research on possible reservoir hosts of yellow fever virus and on *Aedes* and other potential mosquito vectors of yellow fever is being continued. The executive control of yellow fever is the responsibility of the Colonial Governments and the Service authorities, who are advised by and receive copies of the reports of the Director of the Institute and the London Interdepartmental Control Committee. The various control measures which have been introduced are designed particularly to prevent the possibility of an outbreak of yellow fever such as occurred in the Anglo-Egyptian Sudan in 1940-1.

Food Relief for Greece

On Oct. 26 Mr. STOKES asked the Parliamentary Secretary to the Ministry of Economic Warfare whether the supplies of milk and vitamin concentrates included in relief shipments to Greece since April were an addition to the supplies previously permitted to pass through the blockade; and whether he could give an assurance that these supplies fully satisfied the appeals for additional supplies made by the Swedish-Swiss Commission. Mr. FOOT said that the supplies of milk authorized in June represented an increase in monthly amounts previously allowed. The commission in June requested the dispatch of 260 tons of powdered milk or 600 tons of condensed milk a month. It was decided to authorize monthly shipments from July of 300 tons of condensed milk and 300 tons of evaporated milk. This replaced previous monthly allotments of 300 tons. A new six months' programme for vitamins was submitted by the commission in June, which represented in some respects a slight increase in the rate of supplies. These supplies, so far as they were obtainable, were being procured and dispatched.

The White Paper

On Oct. 26 Sir E. GRAHAM-LITTLE asked the Prime Minister whether, as the institution of a universal free health service conducted by full-time salaried medical officers involving ultimate extinction of private practice came into the category of a far-reaching change of a controversial character directly needed for the war effort, he would declare that decisions regarding such a service should not be made without a general election. Mr. ERNEST BROWN, who replied, said that his hon. friend should first await the promised White Paper, so that he might see what proposals were in fact forward in it as the basis for public discussion before he raised the last part of the question.

In a reply on the same day to Mr. Maclean, Mr. JOHNSTON said that the Government was considering the recommendations of the Hetherington Committee in formulating proposals for a new national health service. It was Government's intention, in advance of proposing legislation on the subject, to lay a White Paper on the table of the House on an early date as a basis of discussion and negotiation.

Exchequer Help for Tuberculosis

Mr. JACKSON inquired on Oct. 28 why tuberculous patients considered 'hopeless' cases and those suffering from pulmonary tuberculosis were excluded from the benefit of new financial allowances paid by local authorities. Miss H. BRUGH replied that special arrangements were authorized to enable persons to give up work temporarily for treatment in the interest of the public health no less than their own, in association with the war effort which had been the justification in such cases for making repayment from Exchequer funds under emergency powers was not applicable to the cases which Mr. Jackson referred. That fact did not affect the power of local authorities to grant assistance within the scope of their statutory powers.

Immunization.—Up to June 30 last the total number of children who had been immunized under local authority arrangements in England and Wales was approximately 4,400,000. Allowing additional immunization by private arrangement it is probable substantially more than half the child population is protected at present.

Medical News

Prof. L. G. Parsons will give the first Charles West Lecture before the Royal College of Physicians of London on Tuesday next, Nov. 16, at 2.15 p.m., at the College, Pall Mall East. Subject: "The Prevention of Neonatal Disease and Neonatal Death."

A meeting of the Tuberculosis Association will be held at Man House, 26, Portland Place, W., on Friday, Nov. 19, at 3.15 p.m. for a discussion on immunity-producing measures in tuberculosis.

The Postmaster-General announces that it has been agreed at request of the Treasury to release Sir Henry Bashford, M.F.R.C.P., from the post of Chief Medical Officer to the Post Office in order that he may take up his new appointment as Treasurer and Medical Adviser. Dr. W. L. Scott, M.C., second medical officer, has been appointed Chief Medical Officer to the G.P.O. in succession to Sir Henry Bashford, and Dr. C. G. Roberts, assistant medical officer, has been appointed second medical officer.

At a meeting of the London Association of the Medical Women's Federation, to be held in the Common Room of B.M.A. House on Saturday, Nov. 20, at 3 p.m., Dr. Ian Skottowe will read a paper on some current methods of treatment in psychological medicine. Medical men and women guests are invited.

A discussion on the state of nutrition in enemy-occupied Europe introduced by Lord Horder, will take place at a meeting of the Section of Medicine of the R.S.M., 1, Wimpole Street, W., Tuesday, Nov. 23, at 4.30 p.m. It will be opened by Col. W. Vignal and Dr. A. P. Cawadias, followed by Prof. James Yeaman and Dr. Izod Bennett.

At a members' meeting of the Eugenics Society to be held Tuesday next, Nov. 16, at 5 o'clock, at the rooms of the R. Society, Burlington House, Piccadilly, W., Mr. R. M. Timmuss will speak on "Social Environment and Eugenics." All interested in the subject are invited to attend.

A Diagnosis Section meeting of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Nov. 20, at 10.30 a.m. when papers will be read by Capt. P. P. Hauch, R.C.A.M.C., on pneumoroentgenography of the knee-joint (illustrated by a film); Dr. E. Rohan Williams on venous intravasation during uterine salpingography; and Dr. John Wilkie on a case of Albright's disease followed by a discussion.

The Central London Fabian Society announces that Dr. Stark urray will speak on "A National Health Service" on Tuesdays 7.30 p.m. at the Artworkers' Guild Hall, 6, Queen Square, W.C.1. on 23, "A Personal Health Service" on Dec. 7, "Administration and control" on Dec. 21, "The Ultimate Aim."

At the next quarterly meeting of the Royal Medico-Psychological association on Nov. 24 at 1, Wimpole Street, London, W., a discussion will be held on post-war psychiatry.

A course of instruction for a Diploma in Psychological Medicine will open at the Maudsley Hospital on Jan. 3.

The July number of the *East African Medical Journal*, of which copies have now reached London from Nairobi, is devoted to the actual problem of human nutrition in its most important local aspects. Inspired by the Director of Medical Services in Kenya, sets forth the evidences of malnutrition among some of the native populations, the methods adopted in that colony to deal with the recent shortages of various essential foodstuffs, and the lines along which progress in these matters may best be attempted. There are eight signed articles, prefaced by a judicious editorial, and the whole number reflects great credit on Dr. A. J. Jex-Blake and his colleagues of the editorial committee; it deserves wide circulation in the large area concerned.

The Board of Education announces that by arrangement with the Ministries of Food and of Health supplies of cod-liver oil and orange juice are to be available for administration during school hours to children under 5 years at elementary and nursery schools. Ferrous sulphate tablets, 3 gr., are also to be available for children selected by the medical officer as suffering from anaemia.

For the third winter in succession the Ministry of Health, in co-operation with the Ministry of Information, is launching a campaign to reduce the spread of coughs, colds, influenza, and other droplet infections. The public will again be urged to avoid careless coughing and sneezing. The campaign will continue until March. The Board of Trade will co-operate by including in its "Make do and Mend" advertisements advice on making handkerchiefs out of worn-out sheets, etc. The Central Council for Health Education is again co-operating by offering health leaflets and posters for sale to local authorities.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the incidence of infectious diseases remained steady, with the exception of measles, which fell by 129 cases. The largest of the local decreases were in Kent, by 35, and in Durham, by 31 cases. The rise in notifications of scarlet fever, which had persisted for eight weeks and had resulted in the weekly totals mounting from 1,516 to 3,324, was temporarily checked; 7 fewer cases were reported than in the preceding week.

Notifications of dysentery, which have been high for the last two months, dropped by only 4. The largest of the new local outbreaks were in Glamorganshire, Rhondda U.D. 12; Sole of Peterborough, Peterborough M.B. 11. Big rises in existing outbreaks were recorded in Surrey from 5 to 34 (Kingston-on-Thames M.B. 31), and in Northumberland from 2 to 30 (Newcastle-upon-Tyne C.B. 25). Other large centres of infection were London with 65 cases in twenty boroughs; Middlesex 17; Lancashire 14; Yorks North Riding 14 (Richmond R.D. 10).

In Scotland rises were recorded in the notifications of diphtheria, 35 more, and scarlet fever, 29 more, the totals being the largest during recent months. The increase in diphtheria was fairly general, but that for scarlet fever was mainly confined to the western area. There were 17 fewer notifications of dysentery, and the total, 45, was the lowest since the beginning of June.

In Eire diphtheria notifications went up from 99 to 187, and those for diarrhoea and enteritis from 35 to 93. The largest of the outbreaks of diphtheria was in Limerick (Rathkeale R.D. 61). Of the 95 cases of diarrhoea and enteritis 81 were reported in Dublin C.B.

In Northern Ireland the outbreak of diphtheria in Londonderry C.B. persisted, 14 fresh cases occurring during the week. The Foyle Hill Hospital, which had been closed for a number of years, was reopened to cope with the increase of this disease and scarlet fever. Of the 85 cases of diphtheria notified during October, only 1 had had a complete course of immunization.

The Week Ending October 30

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 3,623, whooping-cough 1,693, diphtheria 702, measles 585, acute pneumonia 576, cerebrospinal fever 26, dysentery 248, paratyphoid 5, typhoid 7.

No. 42

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

ANY QUESTIONS?

Chronic Infective Sinusitis

Q.—May I have suggestions for the treatment of sinusitis affecting the maxillary and frontal sinuses and probably the deeper sinuses? The affection is of some standing. The age of the individual is 50. Is there any drug of the sulphonamide group which is recommended, and if so, what form of drug, what dosage, and what form of administration? Radiant heat and suchlike remedies have already been exploited, with small benefit and improvement for a short period only.

A.—The variety of treatments for chronic sinusitis is a gauge of its obstinacy. It is worth while first finding out by bacteriological examination of nasal swabs if there is a specific infecting organism, of which the most frequent are the haemolytic streptococcus, pneumococcus, *Staph. aureus*, Pfeiffer's or Friedländer's bacillus. The first two of these organisms are more susceptible than the others to sulphonamides, which are more likely to be effective in preventing a flare-up of the sinusitis after an acute coryza than in curing the chronic condition. Sulphamezathine, sulphadiazine, or sulphathiazole in doses of 1 g. by mouth 4-hourly should be given for 2 to 3 days after onset with the patient in bed or resting indoors. Continue with further smaller doses for another 2 to 3 days. An attempt at cure with an autogenous vaccine may be made, and in this connexion it is worth remembering that chronic sinusitis may be an allergic condition, so that dosage should at first be small and carefully graded. If during an acute attack there is obstruction to the discharge with pain over the sinuses, a few drops of 0.5% ephedrine in normal saline followed by argyrol instilled into the nostrils will often give relief. To relieve the chronic nasal obstruction which may be troublesome in the chronic state, giving rise to symptoms of chronic sore throat and bad taste in the mouth, an ammon. carb. or pot. iod. mixture (2- to 3-gr. doses) may be taken in the evening. The patient should be advised about maintaining his general health by regular habits and a well-balanced diet, and he should at all times take more than ordinary precautions to avoid catching colds. (See *B.M.J.*, Sept. 4, 1943, p. 318.)

Physical Training and Female Fertility

Q.—Is there any truth in the belief that excessive physical strain may produce sterility in a woman? I was asked this question recently by a girl about to embark on physical training as a career.

A.—There is no scientific evidence, known to the writer, to support this belief. Many girls who excel at physical training or athletics are naturally inclined to such pursuits by reason of their endocrine make-up. They are sometimes of masculine type, with a muscular, heavy build. Such women undoubtedly tend to have impaired fertility and complicated pregnancies and confinements, but these features should be regarded as further evidence of slight endocrine imbalance rather than the result of physical exercise. If the girl in question is essentially feminine then the pursuit of physical training should not affect her fertility.

Another Rh Question

Q.—Is there any evidence that congenital haemolytic disease is less severe when the birth has been by Caesarean section performed prior to or early in labour—that is, does the process of parturition cause an increased transference of the anti-Rh agglutinin from the Rh-negative mother to her Rh-positive foetus? Likewise is there an increased transference of the Rh agglutinin from the foetus to the mother? It has been stated that the mother's antibody titre is highest between the 7th and 21st days of the puerperium; this would presumably be consistent with an increased transference of the Rh factor from the foetus during parturition.

A.—Rh-negative mothers with anti-Rh agglutinins in the blood sometimes show a fall in the agglutinin titre for a few days after parturition, followed by a sharp rise to a maximum 2 to 4 weeks later. This is thought to be due to an increased transference of Rh

agglutinin from the foetus, probably owing to the escape of blood into the maternal circulation during parturition. A similar explanation is thought to account for the almost constant sharp fall in maternal iso-agglutinins after a hetero-specific pregnancy (Group A mother with Group A or B foetus; A or B mother with B, A, or O foetus). The condition is comparable with that observed in recipient of an incompatible transfusion, where the iso-agglutinin titre at first falls owing to absorption by the transfused antigen, later rises sharply; this is well seen in a mother with anti-agglutinins who is transfused with Rh-positive blood.

Very little is known about the quantitative aspects of the passage of anti-Rh agglutinins from mother to foetus. It is not at all possible to demonstrate them in the cord blood of affected children even when the mother's titre is high, but when demonstrable titre is always lower than the mother's. Such differences have been observed both in natural and in Caesarean births, though number of cases fully studied is small. Caesarean section has been advocated on account of the great liability to intranatal death of foetal asphyxia. Protracted and difficult labour is therefore dangerous, and the lower uterine segment operation under local or spinal anaesthesia has been preferred, since general anaesthesia and use of sedatives are undesirable from their liability to depress foetal respiratory centre. A common cause of foetal asphyxia in such babies is intracranial haemorrhage, to which there is a special liability from the associated haemorrhagic tendency in haemolytic disease of the newborn. There is no evidence that haemolytic disease is less severe when the birth is Caesarean, and the disadvantage claimed for such interference is a diminished risk of complications such as intracranial haemorrhage and foetal asphyxia.

Progressive Muscular Atrophy

Q.—Removal of the thymus gland has recently been advocated in the treatment of certain forms of myasthenia. In view of this would be grateful to learn whether there has been any recent investigation into progressive muscular atrophy, and of any advantage in the treatment of this most heartbreaking condition.

A.—There is no recent work about the treatment of progressive muscular atrophy. Its onset is not related to any disturbance of function at the myoneural junction, but it appears to be a primary degeneration of anterior horn cells, of unknown origin. Treatment is purely palliative, being aimed at conserving the patient's strength. Vitamin therapy has not been proved of use.

Inhibiting Secretion of HCl

Q.—What has been found experimentally to diminish or abolish free hydrochloric acid in a normal stomach?

A.—The secretion of free hydrochloric acid is inhibited by the intravenous or intramuscular injection of urogastrone, a water soluble substance obtainable from the urine of dogs and man. Urogastrone is possibly identical with enterogastrone, a substance which is formed in the intestine when fats are ingested; this also inhibits the secretion of hydrochloric acid on injection. Urogastrone is said to be diminished in the urine of patients with peptic ulcer, and there are good prospects that it may be developed in a suitable form for the treatment of that disease. These effects must be differentiated from those of pregnancy urine extracts, which are likewise said to accelerate the healing of peptic ulcers, though they do not diminish the acidity. Developments may also be expected from current research on carbonic anhydrase. This ferment is present in high concentration in the gastric mucosa and apparently plays a part in the formation of hydrochloric acid. Thiocyanate inhibits equally the ability of carbonic anhydrase to catalyse the hydration and dehydration of carbon dioxide and the secretion of hydrochloric acid by the gastric mucosa of dogs. It would appear that the toxic side-effects of thiocyanate are too great to permit its use for this purpose in man, and it would be well worth while to institute a search for a less toxic chemical with the same or greater power to inhibit the gastric secretion, in the same way as thiouracil and thiouracil were discovered from the systematic study of inhibitors of thyroid secretion.

Unconscious after Head Injury

Q.—A man aged about 70 is found deeply unconscious in his bed one morning. He had had a fall downstairs two weeks before, but had gone about as usual, though he complained of headache. Assuming that his condition might be due to one of the following causes, would you discuss the differential diagnosis and means of investigation: (1) extradural haemorrhage; (2) subdural haemorrhage; (3) subarachnoid haemorrhage; (4) cerebral haemorrhage; (5) cerebral thrombosis. I am assuming that an accident might determine the onset of a cerebral thrombosis. Do you agree?

A.—This differential diagnosis is very satisfactory. By far the most likely condition to have caused the headache and delayed unconsciousness in a man of 70 is a subdural haematoma. This normally gives headaches and a slowly increasing impairment of consciousness without correspondingly severe local signs. The

LETTERS, NOTES, AND ANSWERS

Nov. 13, 1943

story is long for an extradural haemorrhage, but does not exclude a fracture through the temporal bone in this condition might damage to the middle meningeal artery. Subarachnoid bleeding occurs in nearly every head injury and is unimportant unless a simple lumbar puncture could have excluded this. Intracerebral haemorrhage would almost certainly have been associated with long tract signs, and its differential diagnosis from cerebral thrombosis may be very difficult. The headaches for a fortnight before these were not the cause, and trauma does not usually give rise to cerebral thrombosis. In investigating this case I should have done a detailed neurological examination, an x-ray of the skull to look for fractures, and a lumbar puncture, reading pressures. If there was xanthochromia with a rise in protein I should have recommended bilateral exploratory burr holes as soon as consciousness had become impaired. Burr holes should never be omitted in cases of this sort.

Family History of Encephalitis Lethargica

Q.—A girl, now aged 23, tells me that, at the age of 6 she contracted encephalitis lethargica and was admitted to hospital. After five years she was discharged cured—one of the lucky 20%. The amazing thing about her case is that she gives a family history of both father and grandfather who died with encephalitis lethargica. She asks if it is safe for herself, and more particularly for the child, for her to have a baby. I have never heard of this in textbooks. Being hereditary and can find no reference to this in textbooks. The girl has been examined by myself and at a hospital, and physically she is perfect. She has an attitude and way of speaking which is a trifle "lethargic," but passably normal.

A.—Encephalitis lethargica is an infection and therefore cannot be inherited. It is caused by a virus, which can remain alive in the brain for many years, and some viruses can be transmitted from parent to child in the ovum or spermatozoon. The history of this patient suggests that the virus of encephalitis lethargica may be transmitted in this way, but, if so, it must be a very rare occurrence. I do not remember any example of a parent and child having had encephalitis lethargica, and I am sure I have never heard of one in which three successive generations were affected. I think that if this patient has a child the risk of it developing encephalitis lethargica is too remote to be considered seriously.

Treatment of Vulval Warts

Q.—Can you help me to treat a crop of gonococcal warts on the labia majora of a young woman who has just been confined? She acquired this disease during pregnancy (from her husband), was treated and reported cured. The child is free from disease and the mother has no signs or symptoms other than this crop of irritating warts. I do not want to send this girl back to a V.D. clinic unless it is necessary.

A.—Vulval warts tend to flourish during pregnancy; now that the confinement is over and there is no gonorrhoeal discharge they may begin to regress. The first thing to do is to allay them and bathe the affected parts with weak antiseptic; then dry them and keep them dry with a dusting powder, such as zinc oxide, boric acid, and bismuth subgallate, equal parts. If this does not cause disappearance, various local methods may be tried: (1) Paint frequently with: liq. arsen., 1 part, vin. ipecac., 1 part, sp. vin. rect., 2 parts. (2) Touch the warts with either nitric acid or trichloroacetic acid, or with a mixture of salicylic acid, 1 part, acetic acid, 8 parts; the neighbouring skin should be protected with vaseline and the labia majora kept apart with a piece of lint. (3) Destroy with electrocautery. (4) Coagulate with the diathermy current. A few move the warts by scraping with a curette or sharp spoon. A few applications of superficial x rays are often useful in preventing recurrence, which is common; these should be carried out only by an expert.

Much depends on how big a crop of warts has to be dealt with. Mild measures will usually be effective if the warts are few and scattered; more drastic ones are indicated if there are large masses. Warm, moist conditions favour the growth of warts, and warts are infective. In carrying out treatment these facts should be borne in mind.

Myopic Schoolboy

Q.—A schoolboy between 13 and 16 has myopia of mild or moderate degree. An oculist prescribes suitable lenses so that he can see at a distance. The boy is then told only to wear the glasses for near work or intense gazing at a distance, such as the blackboard. The usual result is that the boy keeps his glasses in his pocket and does not remember to wear them at all unless he really needs help for distant vision; he may then remember to use them. No boy wants to be seen in spectacles. The only value of the glasses, so far as I am aware, is to enable him to see at a distance. There is nothing curative about them. With them he can see birds, recognize his friends, watch the cricket, see the school clock across the quadrangle. Without them he misses all these things, whatever he may say to persuade one to think that he can

see well. If he always wore them he would not feel self-conscious for long. Why, therefore, tell him that he only needs to wear them on occasions? Some specialists tell him to wear glasses for reading, when he knows for himself that he does not need them. Is this on the assumption that it is close work which goes with study at schools that is the cause of the myopia? I am entirely in the dark as to the rationale of the modern treatment of myopia. It seems unreasonable to assume the condition is due to study, entirely wrong to wear glasses for near work, and psychologically unsound to start off by minimizing the occasions for which spectacles are to be used. I should be grateful if I could be put right in this matter.

A.—In myopia of a very mild degree it is better to be circumspect in prescribing glasses. The wearing of glasses by a scholar has a psychological effect dependent upon the make-up of the child. In cases of very slight myopia where the mental effort is likely to be marked it is better to await events. This, in practice, is found to be wise: for though glasses would benefit distant vision to some extent, the child can see the blackboard well enough without them, aid if he is in the front of the class, and he can see to read slightly better than with glasses. In these circumstances it is more than likely that any glasses will be kept in the pocket. The parents should be warned that myopia tends to increase with the growth of the child and that glasses may be required later. Where the short-sight is sufficient to prevent clear and easy vision of the blackboard from any position in the class, glasses should be ordered and should be worn all day long. With the exception of football and swimming this rule should be rigidly adhered to, otherwise the glasses will not be put on when they should. Unsplinterable lenses used to be ordered for games, but at the present time there is some difficulty in obtaining the safety glass. Plastic lenses are very light in weight and meet the case, but are rather easily scratched. At one children's clinic there has been only one case of splintering with ordinary glass in about 13,000 spectacles.

Glasses in myopia cannot be curative—there is no recognized cure of myopia—but there is a great weight of opinion that they limit the usual increase. Two factors must be considered when a moderate myope reads without glasses. First, the head is held too close to the book. This necessitates over-convergence of the eyes and consequent undue pressure by the eye muscles on the globe of the eye, tending to accentuate myopic elongation. Secondly, it is said by some that a congestion of the eye is engendered which is deleterious. The habitual stooping may also affect the carriage of the child. The wearing of the proper correction entails the use of the ciliary muscle when reading, with a consequent improvement in the intra-ocular circulation. In other words, the eye is being used as intended by Nature. The myope reading without glasses exercises little or no focusing (hence the popularity of dispensing with glasses), and atrophy of the ciliary muscle of a corresponding degree results.

To sum up: very slight myopia—no glasses, from the practical and psychological points of view: other degrees of myopia—glasses for constant wear.

Intractable "Athlete's Foot"

Q.—May I have suggestions for the treatment of an intractable case of "athlete's foot"? A patient contracted this complaint two years ago. He was first treated with the usual fungicidal ointments, to which later skin-healing ointments were added in order to get deep penetration, as the lesion seemed very deep-seated. X rays were later applied, with beneficial results for one month. After this, in spite of the application of new dye preparations, the lesion continued to spread. As a last resort I used carbolic to strip the skin deep, and reapplied dyes. I am now trying azochloramid, but so far results don't look very satisfactory. The condition now occupies all the sole of the foot except the heels, toes, and base of toes, and shows a tendency to spread up the medial surface of the foot.

A.—Although "athlete's foot" usually means ringworm, it also has a popular application to a variety of symptoms which may or may not be parasitic. Dermatologists are well aware of the refractory nature of a proportion of the ringworm infections of the foot, and have attributed this to the difficulty of getting at and destroying the fungus in the thickened white skin between the toes or to reinfection from diseased toenails. This difficulty is reflected in the very numerous "specifics" which are put on the market from time to time.

Eczematoid ringworm of the foot was first recognized and described in France in 1892 by Djelaleddin-Moukhtar and was elaborated by Sabouraud and other workers long before its nature was appreciated elsewhere. It is thus essentially a European complaint, although more common in the United States. The qualifying term "eczematoid" is significant because it calls attention to the eczema moiety of the eruptive process, which is often aggravated by the strong fungicides, which convert a simple process into an extensive eczema. In view of this it may be well, in the circumstances related by the questioner, to discontinue all active treatment and use simple measures suitable for acute eczema, such as boric zinc ointment and lead calamine lotion. When it becomes possible

a search for fungus in the skin between the toes or elsewhere should be made, as it is possible that the fungus has been eliminated by the previous treatment.

Epidermophytosis

Q.—Is there any known cure for chronic and intractable trichophytosis of the hands and feet?

A.—Presumably the question refers to epidermophytosis of the hands and feet. This can be very nearly impossible to cure. In my experience the most valuable remedy is dithranol as a 2% solution in benzene (B.P.), or in the form of an ointment from 2 to 4% in strength, preferably in an emulsifying base. Owing to its staining and irritating effects, dithranol has to be used with caution.

Paget's Disease Again

Q.—Can anything be done for a case of Paget's disease of the bone in a man aged 46? He has the usual gross thickening and sclerosis of bone in skull, pelvis, femurs, lumbar and dorsal spine. He has been treated with ultra-violet light, suprarenal extract, and many other remedies, without benefit. His chief complaint is that he cannot stand upright for more than a few moments because of the pain which runs down his back and into his legs, the pain being a rather unusual constant feature in his case.

A.—As stated in our previous answer about Paget's disease (Oct. 16, p. 501), in all such cases it is important not to allow the spectacular appearances in the radiographs to take attention away from other possible causes of symptoms. Spinal tumours and other lesions possibly causing referred pain to the legs must be satisfactorily eliminated. At the same time it should be remembered that a certain number of cases of Paget's disease undergo sarcomatous change. Radiotherapy, if nothing else is found, should be tried.

LETTERS, NOTES, ETC.

The Tobacco Habit

Sir HAROLD SCOTT (Braintree, Essex) writes: Referring to the question on page 502 of the issue of Oct. 16 concerning a cure of the tobacco habit, may I suggest a remedy which I have found efficacious, first with myself and later in other cases of those who have wished to stop the smoking habit? It is to rinse the mouth with a solution of 0.25% silver nitrate. I believe that I originally got the idea from the *British Medical Journal*, but it must have been at least thirty years ago.

Treatment of Sweating Feet

Surg. Capt. D. H. C. GIVEN writes: The following method of treating sweating feet, introduced by the factory chiropodist almost 12 months ago, has proved most successful. Many of the patients returned to report that it was the first remedy after years of suffering that had brought real relief and cure. Procedure is as follows. Apply a lotion of 3% salicylic acid in a spirit base to the affected parts t.d.s., allowing it to dry off before replacing the footwear. A small quantity of the following powder should be dusted daily into the socks: salicylic acid 3 parts, starch powder 10 parts, talcum 87 parts. Improvement is usually manifest in three to four days, when the application can gradually be reduced to suit the case.

Dr. ASTLEY V. CLARKE (Leicester) writes: During the last war we also had the problem of sweating feet and tried all sorts of remedies. We came to the conclusion that proper ventilation of the feet—that is, boots not too tightly fitting—together with daily washing of the soles with soap and either a nail brush or, better still, a pumice stone to rub the soap well in and remove sodden epidermis, was the simplest and was very effective. We found the men had never washed the sole of the foot with soap, as to do it is rather a gymnastic performance. In civil life, too, this treatment is all that is necessary in most cases. Forty years ago sweating feet among young women out-patients was very common, but this is almost unknown now that thin stockings and shoes give the proper ventilation. The same girls often had chlorosis, and removal of the stays they wore then has, I believe, been a potent factor in the disappearance of chlorosis.

Dr. ALBERT W. BAUER writes: Referring to the suggestion made by Capt. E. Colin Jones (Oct. 30, p. 558) on the treatment of sweating feet I take the liberty of calling attention to the treatment used in the old Imperial Austrian Army, which is still simpler, and proved very effective not only in combating sweating feet but also the spreading of furunculosis by contact and dressing to which soldiers (and civilians) often are subject through uncleanness caused by the impossibility of changing stockings and underclothing, etc. The treatment consists of painting the soles and spaces between the toes and/or the area where furunculosis is present with a 10% aqueous solution of formalin for three days daily and then once or twice weekly. By this painting the skin is tanned and so hardened against spread of infection. The actual furuncle is, of course, treated as usual. Here, too, a little supervision is necessary to prevent the skin

from getting too dry or too irritated. An aqueous solution of formalin contains about 40% of formaldehyde; to avoid error, prescription must be made by using the chemical formula—40% of H.CHO.

Recurrent Erysipelas

Dr. H. W. BARDER (London) writes: With regard to the case of recurrent erysipelas referred to in the "Any Questions?" column (Oct. 23, p. 533), I should suspect that the source of the recurrent invasion of the lymphatics is one or more streptococcal fissure the retro-auricular fold, or possibly at the entry of the meatus. This is so, no treatment is likely to prevent the attacks unless fissures are permanently healed. Recurrent lymphangitis (relapsing erysipelas) is one of the most important and serious complications of chronic streptococcal infection of the skin, because the repeated invasion of the lymphatics may eventually cause their blockage giving rise to persistent elephantiasis and permanent disfigurement. In these cases the attacks of lymphangitis are seldom accompanied by much rise in temperature, and the general disturbance is slight. This is as one would expect, since the patient is a chronic streptococcal carrier, and the strain of organism is not virulent. Fissures occur in the natural folds of the skin as a complication of chronic streptococcal intertrigo, or at muco-cutaneous junctions. For brevity's sake the cases may be classified according to site involved in tabular form:

Site of the Lymphatics	Portal of Entry to the Lymphatics	Comments
1. Nose, malar regions, and lower eyelids	Fissures at the angles of the nostrils, often associated with impetiginous anterior rhinitis, chronic nasal catarrh, and sometimes with sinusitis	If elephantiasis superimposed on the condition known as "erysipelas periorificial" (Kaposi) or "oedema" (Hutchinson) results
2. Ears, adjacent parts of the face and scalp	Fissures in the retro-auricular space with chronic streptococcal intertrigo, which may in turn be secondary to a seborrhoeic dermatitis spreading from the scalp; or chronic meatitis, with fissures at the entry to the meatus, also often primarily a seborrhoeic infection	Persistent elephantiasis of the pinnae may be a sequel
3. Lips	Fissures in the vermilion borders of the lips with chronic cheilitis, or at the labial commissures	Persistent lymphatic oedema of one or both lips is relatively frequent, and extremely difficult to influence by treatment
4. Scrotum and perineum	Chronic streptococcal intertrigo of the internal cleft with radiating fissures in the anal folds, over the coccyx, and in the median raphe of the scrotum	In these cases large numbers of pathogenic streptococci may be cultivated from the stools. Elephantiasis of the scrotum is not uncommon
5. Dorsum of the foot, ankle, and leg	Fissures between the toes, or a chronic paronychia	The streptococcal fissure almost always a complication of interdigital dermatophytosis, treatment of which is essential, attacks of lymphangitis in this situation may be accompanied by a considerable pain and malaise. Persistent elephantiasis of both legs may gradually become established. This is the most serious complication of epidermophytosis of the feet

These are the commonest sites at which relapsing lymphangitis occurs, but not the only ones. I have, for example, seen the wall involved in a woman with submammary intertrigo. The recognition of the nature and origin of this form of relapsing erysipelas, which is a clinical entity in itself, has led to many persons unnecessarily disfigured and even partially incapacitated. Its treatment is a chapter in itself.

Parodontal Disease

Dr. BRIAN BOYD-COOPER (the Royal Dental Hospital of London) writes: In the *Journal* of Oct. 23 (p. 534) I was much interested to read the answer given by your correspondent under the heading "Any Questions?" dealing with the query on the treatment of parodontal disease. I should like to congratulate him on the able and succinct and sound advice he has given. There is, however, a startling omission—namely, there is no mention of securing the collaboration of the dental surgeon in such a case. Your correspondent wisely states that "local treatment is of more value than general." Surely this is within the province of the dental profession, to whom such procedures as are suggested more naturally belong?

* We agree.—Ed., B.M.J.

LONDON SATURDAY NOVEMBER 20 1943

SOCIAL MEDICINE: ITS MEANING AND ITS SCOPE

BY

JOHN A. RYLE, M.D., F.R.C.P.

Professor of Social Medicine in the University of Oxford

"Salus populi suprema est lex"

There has been much discussion in the medical journals and the daily press in recent months as to the purport and prospects of social medicine. In the minds of some of the profession there would appear to linger a confusion of thought as to the meaning of the term; some uncertainty even as to the underlying ideas which have prompted the discussion. The laity and members of the social services and student bodies are eagerly seeking enlightenment; less harassed and preoccupied and, perhaps, more hopeful of the future than the overworked doctor, they have sometimes appeared more receptive and understanding than the profession whose intimate concern these ideas must shortly become. The prevailing uncertainties would seem to be based upon two main misconceptions: (1) that social medicine is just another name for preventive medicine as we now know it, and (2) that social medicine and socialized (or State) medicine are synonymous. It seemed to me that it might be helpful to trace the sources of these misconceptions and to attempt a brief account of what the actual meaning and objectives of social medicine are in the view of those who have, for longer or shorter periods, insisted on the need for an evolutionary change in much of our general teaching, philosophy, and practice.

A Recent Awakening

We are most of us conscious of the fact that medicine during the past quarter of a century has become (inevitably, be it allowed) not merely more specialized but also more technical, and that in the process—for the technicalities are often precise, intricate, and time-consuming—the old aetiological interest and humanism of our fathers have tended to take a second place. In the teaching hospitals this can scarcely be disputed. Investigation to the limit, mainly by objective methods and often with too little said to or done for the patient during or after the tedious process, has been the prevailing trend, especially in the case of the more chronic or seemingly more obscure varieties of disorder and disease. More and more accurate assessments of local pathology, with the help of more and more colleagues and instruments, and less and less intimate understanding of the patient as a whole man or woman with a home and anxieties and economic problems and a past and a future and a job to be held or lost, have become the order of the day. As we direct our students, so in large measure must the outlook and method of each new generation of doctors be determined. Over-reliance on specific objective tests; too strong a belief in the potency of certain treatments aimed at altering established disease-states or too deep a despair at the apparent unalterability of others; too little knowledge of morbidity and mortality figures, of the relative incidence of diseases in the community, of the vast prevalence of "illness" or "debility" without "physical signs" and of their several significances; too vague an appreciation of the fact that these illnesses and, indeed, many of the organic

diseases have discoverable origins in social, domestic, or industrial maladjustment, in fatigue, economic insecurity, or dietary insufficiency—have not these already set their stamp upon the work and outlook of the younger generation of practitioners? And are the majority of those who teach them, most of whom have but little close acquaintance with the conditions in which their poorer hospital patients live and work, much wiser? There are notable exceptions, it is true, but their numbers dwindle. The sciences and techniques have come to dominate medicine to the exclusion of the most important science of all—the science of man—and the most important technique of all—the technique of understanding. Science without humanism may work with atoms but it will not work with men.

In the United States, where this "mechanized" medicine has perhaps captivated the thought and action of the doctor even more than in this country, there has been a recent awakening to the need for a return to the older methods of study and assessment, the methods of the general physician—the methods which the writings of a Trousseau or an Osler were ever at pains to describe but which are often barely mentioned in modern textbooks. Canby Robinson (1939) has told how at Johns Hopkins it was found necessary to launch a new experiment with a physician and assistants to stand in a special personal relationship to the patient—a relationship which all the specialists and interns responsible for his more specific investigations and treatments somehow failed to achieve. With the aid of the trained medical social worker and with closer collaboration with the departments of public health and assistance, the interdependence of clinical, social, and environmental studies and the contribution which each can make to a better appreciation of aetiology and prognosis and to a better organization of after-care are now being taught to the student in several of the American schools. Visits are made to the environment in which illness has had its beginnings. Tuberculosis and venereal disease are being considered as human, educational, and social problems; and not merely as medical and surgical problems with their set routines for diagnosis and therapy. The neuroses and psychoneuroses, it is found, are often better helped by these new alliances than by calling yet another specialist to the bedside while the physician or surgeon, who has "excluded organic disease," retires from the scene with a sigh of relief for something accomplished—even though it was a "negative" something where the patient was concerned.

Causes of Misconception

Unprofitable trends in clinical teaching and research, educational errors at various stages in the curriculum—quite as much as its overcrowding—would indeed seem to be among the initial causes of misconception, of the failure to appreciate what social medicine, a direct development and expansion of clinical medicine, seeks to provide for the student and for the individual patient and for those closer and more useful relations between the people and their medical services which we would all like to see established. For social medicine, as its name implies, clearly has a main concern with the group as well as the individuals composing the group, with the many and varied problems created by sickness in the family and the community as a whole. The illustrations or texts

for the contributions which it makes, or at present fails to make, are often to hand in the ward and out-patient clinic, and should be first presented there, but there are many larger problems to be explored "in the field."

The Third Epoch of Preventive Medicine

We are living to-day at the end of the second (or the beginning of the third) of the three great historical epochs of preventive medicine in this country. Starting a hundred years ago with Chadwick—followed a little later by Parkes and Simon, Southwood Smith and Farr—the first epoch was occupied with the disclosure of the appalling conditions in which the working classes then lived, of the prevailing lack of sanitary provisions, of the hovel-like homes, of the defective and contaminated water-supplies; of the high death rates; and with the earlier endeavours to limit the ravages of the acute infectious diseases—typhus, typhoid, smallpox, cholera, and the malignant scarlet fever of those days.

The second epoch has continued and extended the work of the first, but it has also witnessed the attack on the chronic infective diseases—tuberculosis, venereal disease, and now (we may hope), with an improved understanding of its intimate connexions with poverty and crowding and streptococcal throat infections, on rheumatic fever, which (with chorea and rheumatic heart disease) remains second only as a cause of death to phthisis between 5 and 45 in women and follows phthisis and violence in men (Morris and Titmuss, 1942).

The idea that many non-infective diseases can also be considered as preventable and so may eventually be brought within the jurisdiction of a nation's health authority has sunk more slowly into the consciousness both of the profession and of the laity. But before our eyes and in the space of four years of war we have seen the work of the great students of nutrition bear fruit, a Ministry of Food established, and our people as a whole in better health through better feeding, in spite of many shortages, than they were in times of peace. Measures to secure better standards of nutrition, better housing, and better education, and to reduce industrial fatigue and hazards (although in all these directions we still have a long way to go) have marked the beginning of our third epoch. In this period we have realized not only that many non-infective diseases (including rickets, chlorosis, other nutritional anaemias, and much retarded physical and mental development) are readily preventable, but also that by preventing them and raising the general standards of health—*especially in early life*—we assist indirectly the attack on morbidity and mortality due to the diseases of infective origin (including tuberculosis and, in all probability, most of the acute infectious fevers of childhood). Universal pasteurization of milk and an extension of diphtheria immunization could carry us a stage further.

There remain, however, other diseases in plenty which must be regarded as in large degree preventable through socio-medical reforms: diseases which are associated with faulty habits of life or conditions of living; diseases too which are, in our existing order, becoming yearly more prevalent. Of such, for example, are gastric and duodenal ulcer, now greatly on the increase, and the psychoses. Peptic ulcer in the industrialized countries is competing with tuberculosis and rheumatic fever, not as a cause of mortality (although that is serious enough), but as a cause of sick-wastage, of chronic or recurring disability affecting men and women at the time of life when they should be most useful and most active and their responsibilities are greatest. It affects certain physical and temperamental types more than others; it affects all social groups, but whether equally or unequally we do not yet know. It is a disease notably of the latter half of the industrial era, the era of money-getting and money-lack, of occupational and domestic anxiety, of wars and rumours of wars, of restless living and "snack" meals and excessive tobacco consumption. Its therapeutics leave much to be desired. Its prevention has not been seriously considered. In common with other non-infective diseases it has not come within the scope of our present public health organization. What was once a relatively rare disease can, however, become so again when our work and our social and individual lives are better planned.

The same factors which have increased the incidence of peptic ulcer and a prominent group of visceral disorders commonly described as "psychosomatic" (an unsatisfactory title, since all diseases have their physical and mental components) have been partly responsible for the prevalent psychoneurosis in the community. Faults of upbringing, domestic stress, industrial fatigue,

inadequate sleep and holidays, economic anxieties—factors equally alterable by improved education, more ample accommodation for families, factory welfare, and social insurance—have played their significant part. In the meantime we try to cope with their consequences with bottles of medicine and certificates a multiplication of psychiatric clinics at an ever-increasing cost to the community.

Endemic goitre persists in many rural areas along the goitre belt of England. We know that it is largely preventable and that it has been partially controlled in other countries, but have not yet taken purposeful steps to control it in our own. Even cancer, quite apart from its occupational varieties, has its social or class distinctions, for deaths from cancers of the surface and of the stomach and upper alimentary tract are approximately twice as common among the poor as in the more privileged sections of the community. Dental disease (almost unknown in some native communities almost universal with us, but in its graver forms common among the poor, and has many serious secondary consequences.

A Socio-Medical Problem

Good food and habits of feeding, good houses, better facilities for open-air activities and cleanliness, better education and cultural opportunity, holidays and social security—could they be extended to the populace as a whole—would bring benefits, both human and economic, to the individual and to the State beside which the accruing from all our remarkable advances in remedial medicine and surgery of the last century, valuable though they have and must remain, would make but a poor showing.

The evidence for such contentions is already available in extensive statistical studies of the differential mortality figures as disclosed in the Registrar-General's records, relating to the five main social groupings; and mortality is only a very partial index of morbidity. Whether we consider deaths from tuberculosis or rheumatic fever, disease or the infantile death rate, the figures mount steadily; they are traced from the economically favoured classes to those of the lower-income groups. Notwithstanding that there has been a satisfactory downward trend in infantile mortality—always a crude index of social condition—in each of these social groups, there is some evidence for an increasing disparity in the mortality rates as between the highest and lowest groups (Titmuss, 1943). According to our national statistics for the period 1930-2 the disparity in mortality in the first month of life as between the best and worst economic grades was of the order of 50%, but in the latter phase of post-natal life (i.e., 6 to 12 months) the difference was as great as 439%. Before the war the infant death rate in some of our northern industrial cities was as much as three times that in certain suburban districts of Surrey, and British figures compared unfavourably with those from other progressive countries. The bearing of all this on national efficiency and happiness and on the population problem need scarcely be stressed. Outside the relatively small "social problem" group there is no good evidence of genetic inferiority among the poorer classes. The situation should therefore be regarded as susceptible of ultimate amendment by economic and environmental changes.

These and other cognate findings concerning the influence of class, occupation, or geography on health have been frequently reported upon by our leading statistical authorities. They are available in papers or publications by Major Greenwood, Peckham, Stocks, Bradford Hill, H. M. Vernon, and many others in this country, and in various reports prepared for the Medical Research Council. But the lag between discovery or demonstration and action is ever a long one. Here, however, is a socio-medical problem, a situation which we cannot lightly accept and of which we should all be more than vaguely aware. Of the mass of non-lethal disease, much of it alterable or avoidable, we have no reliable records, but the Peckham Health Centre experiment (1938) and family studies have given us a disturbing picture of the extent of urban unfitness and have suggested some of the measures which could help to lessen it. *Our Towns: A Close-up* (Oxford University Press, 1943) and other wartime revelations have also thrown light on dark places for the general public and for those of our profession whose particular experience has been remote from the lives of those who work in slum or factory or mine or who man the ships of the great but grimly unhygienic merchant navy. A more detailed knowledge of these things—in brief, of ultimate causes—is surely as much due to the medical student and the practitioner as to the detailed knowledge of bacteriology or morbid anatomy. If it

are ill informed, or if their own experience in the social and medical fields remains too limited or uncommunicated, how can we expect the people, as voting citizens, and their municipal or parliamentary representatives to know and act?

And how much yet remains to be done in the shape of combined medical and social inquiry! At present we have no reliable morbidity (as distinct from mortality) statistics apart from those relating to the notifiable diseases. Nor have we sifted, as carefully as we shall have to sift, the particular influences operating within the three main adversities due respectively to low economic, environmental, and educational standards. Nor have we seriously begun to study health itself within its considerable ranges of variation for age, sex, and occupation, or to determine the manifestations and standards which distinguish the individual in "full health" from the individual with "no demonstrable disease" or with early illness. We have much to learn from periodic health examinations and the study of fit groups in childhood, adolescence, and later life, and especially in the schools and Services. Growth and development in differing environments await a much fuller investigation. There is no lack of material for the student of social disease and disability, and of those states of physical, mental, and moral health or "wholeness" which must provide the target for our human planning. While disease accompanying poverty and manual toil provides a problem of far greater magnitude it should also be remembered that there are diseases of affluence or due to professional overwork and anxiety which better education and individual discipline and hygiene could conspicuously reduce. Man and his heredity, his types, and his reactions to environmental stress are inexhaustible studies.

New Training and Opportunity

But enough, perhaps, has been said to explain why social medicine—no new concept and certainly not a new specialism, for its principles have long been germinating in the minds and reflected in the motives of all good practitioners and health officers—has required and received its new impetus; enough, too, to indicate its wide scope and that it envisages something far more comprehensive than our existing preventive medicine. It is a concern of all branches of our medical and health services, remedial and environmental, and of their ancillary services, and, among these in particular, of the hospital and municipal social worker. It must eventually invoke, through health education as an essential part of a broader general education continuing into adult life, the co-operation of the public as a whole. Its teachers, although special appointments in medical schools and institutes will be required in due course, must come to include all teachers of the main clinical subjects. Social medicine is indeed a necessary interest of the general physician, whose numbers within our schools must surely be increased and whose demonstrations could often be both clarified and amplified by fuller and more frequent references to initial or basic aetiology, and to rehabilitation and subsequent care, as an offset to concentration upon particular pathologies and immediate treatments. The co-operation between clinical teacher and hospital almoner (as social worker) in ward and clinic must become much closer.

The students and investigators of social medicine have long been active, and will continue to be found especially among the epidemiologists and medical statisticians; they will be found among the workers on human nutrition, on industrial psychology and industrial and domestic fatigue, and on maternity and child welfare; or among Service medical officers with their fine opportunities for studying large bodies of fit men or men in the process of being trained and fed to a finer level of physical and mental efficiency and resource than their civilian lives allowed; and, last but not least, among all those physicians or surgeons whose interest has led them to the study, in home and clinic and hospital, of the broader natural history of man in disease (or health); of man as he continually reacts, emotionally and physically, not merely to the single noxious agent but to the multiple circumstances of his whole life and environment. For such as these and others with other problems our departments of social medicine will come to provide new training and opportunity.

The practitioners of social medicine will, it need hardly be said, eventually include the whole of the practising part of the profession as well as the officers of the environmental services. There is no sharp division between individual and social medicine. Health education and periodic health examination will some day

supplement the remedial activities of the general practitioner, and co-operation with his colleagues of the public health service will be a far closer one than it is to-day.

The Physician's Mission

And, finally, what should be said of the confusion which has arisen in some minds between social medicine and socialized or State medicine? Although social medicine and the planning for a comprehensive medical service, through the stimulus of the times we live in, have come simultaneously under review in the medical and the general press it should be abundantly clear, from what has gone before, that social medicine has no immediate concern with medical or other politics. That it will (in common with all other scientific and educational developments having a bearing on human betterment) influence legislation and prompt reforms in the fullness of time cannot be disputed. Jenner's observations and experiments were a precursor of compulsory vaccination. Osler's teaching expedited the attack on typhoid and tuberculosis. Without Gowland Hopkins, Edward Mellanby, John Boyd Orr, and others of our own day it may be doubted whether we should have had school meals or Lord Woolton and a Ministry of Food which—in our crowded island and in the midst of a long world war—has helped already, by legislation and organization, to improve the general state of fitness of the people.

There are those, it is true, who feel entitled to believe that social and individual medicine will find a better opportunity under a reorganized, co-operative and comprehensive medical and health service in which the uneconomic and often inequitable separations into "voluntary and municipal," "private and panel," and "preventive and remedial" services will no longer obtain. But the advocacy of changes of this kind is no more a function of social medicine than, let us say, the nationalization of the chemical industries is a function of the chemical sciences, or the framing of new regulations for the mines a duty for the Medical Research Council's Committee on Silicosis.

It may properly be argued that many of the social evils, so widely manifest by disease, which have been cited above call not for medical action but for drastic social and economic reform. For these the electorate through their representatives, and not the doctors (as doctors), must become responsible. But who unearths and exposes the evils and their secondary effects? The factual evidence, the socio-medical experience, the statistical data—all of which must be carefully and laboriously collected and analysed—must continue to be provided by the doctors and their scientific associates and field-workers and particularly by those whose concern is rather with the social than with the individual aspects of disease. Whether in this basic manner, or more immediately as an educator of opinion, or incidentally in the course of his daily professional activities, we have reached a time in which "the physician" (to quote Prof. Sigerist) "must assume leadership in the struggle for the improvement of conditions." Without research and teaching in social medicine to guide him he cannot faithfully fulfil his mission.

Conclusion

In summary, social medicine means what it says. It embodies the idea of medicine applied to the service of man as *socius*, as fellow or comrade, with a view to a better understanding and more durable assistance of all his main and contributory troubles which are inimical to active health and not merely to removing or alleviating a present pathology. It embodies also the idea of medicine applied in the service of *societas*, or the community of men, with a view to lowering the incidence of all preventable disease and raising the general level of human fitness.

As one who has been made responsible for the first institute of social medicine in this country and whose training and teaching for more than 25 years have been essentially clinical, I should like to add that I regard social medicine (for all its needful associations with public hygiene) as a logical development from and a direct expansion of clinical medicine, of medicine construed in its best Hippocratic sense and activated by the highest Hippocratic ideal; for "where there is love of man there also is love of the Art."

Of the work and intended programmes at Oxford it is too soon to speak, for they are but in their infancy. Suffice it to say that the Institute already houses the Oxford Nutrition Survey and is about to house one of two experimental bureaux supported

by the Nuffield Trust (the other based on Glasgow) for the collection and analysis of morbidity statistics; that it is sponsoring some studies of endemic goitre in rural England; and that its director and his colleagues have recently initiated regular socio-medical teaching and demonstrations (with the help of the hospital staff and social workers) for students in their clinical years at the Radcliffe Infirmary. Close co-operation with the Institute has been generously offered by the public health authorities of the city of Oxford and of the county. For our team of graduate assistants we shall have to wait until demobilization provides them with their opportunity for new service and us with a new stimulus.

To those in our universities or health departments, in practice, or serving with the armed Forces who are interested in these things and in the needs of the future it seems that the ideas and tasks of social medicine may be justly regarded as essential contributions (perhaps the most essential and practical of any at present within our range) to the developing philosophy of scientific humanism. The potentialities of this philosophy are very great. Wherever our science, our faith, and unpredictable chance may lead us it can now scarcely be doubted—even while the present mad epoch of destruction continues—that we are moving upon the borders of new and possible worlds. To the rational and humane enrichment of these worlds the profession and the sciences which have the most intimate concern with man himself—a very social animal—have surely much to offer. To envisage and design a close equality of opportunity for health in the coming generations is no longer an extravagant fancy. Whether at home, in India or the colonies, or in the broader international field, it may shortly become our most urgent common interest. Nor should we forget that in our Dominions and other countries, and notably in the land of our most virile and victorious ally, there have been important experiments in social medicine and hygiene from which we have much to learn.

THE THERAPEUTIC VALUE OF GAS-GANGRENE ANTITOXIN*

BY

M. G. MACFARLANE, Ph.D.

Secretary, Subcommittee on Anaerobic Wound Infections

as gangrene is characteristically a disease due to the invasion of tissues and the production of toxins by anaerobic bacteria of the Clostridium group present in infected wounds, particularly in wounds involving muscle, the most rational treatment appears to be a combination of measures—the use of surgery and bacteriostatic drugs to control the infection, and the use of antitoxin to alleviate the toxæmia. The War Wounds Committee of the Medical Research Council accordingly recommended (*M.R.C. War Memorandum No. 2*, 1940) that antitoxin should be used in conjunction with surgery and chemotherapy in the treatment of gas gangrene, the procedure then advised being the intravenous injection of 13,500 units† of polyvalent antitoxin as soon as possible after diagnosis, repeated according to the signs. In order that the value of this and other lines of treatment could be assessed, surgeons were asked to make detailed returns of all cases of gas gangrene and of lesser anaerobic wound infections on the forms issued (Army Form I 1241 and its supplement I 1241A). Through the courtesy of the Medical Directors-General of the three fighting Services and the E.M.S. the

returned forms have been made available for study, and enough data have now accumulated for a preliminary analysis of the therapeutic value of antitoxin.

Evidence of the value of the specific antitoxins in the treatment of gas gangrene developing in wounded men was brought forward by Weinberg and Séguin (1918); promising results were also obtained in 1918 by British workers (Medical Research Committee, 1919). MacLennan (1943a, 1943b) has recently made a detailed report on the clinical and bacteriological features of the anaerobic wound infections encountered in the Middle East Forces, in which he discussed the value of the various lines of prophylaxis and treatment. His demonstration that in a group of patients which comprised 70% of all the cases of true gas gangrene reported in these Forces the fatality rate was significantly lower among those who had received antitoxin provides further evidence of the therapeutic value of polyvalent antitoxin in field conditions. The present survey is based primarily on all the reports (259) of anaerobic wound infections received by the Medical Research Council up to June, 1943, excluding those from the Middle East Forces, and is concerned only with the value of antitoxin in the treatment of established cases of gas gangrene. The question of its prophylactic value will not here be discussed; it will only be repeated, as MacLennan has already pointed out, that the prophylactic value cannot at present be determined, as the necessary information on the number of casualties that have received this prophylaxis and have not developed gas gangrene is not yet available. The occurrence of gas gangrene in a patient who has received antitoxin soon after wounding is an individual failure of prophylaxis which is without significance, in a statistical sense, until the total number receiving this prophylaxis is known.

Object of the Present Analysis

It is not to be expected that gas-gangrene antitoxin will be of value in the treatment of anaerobic cellulitis and lesser clostridial infections without toxæmia. In order to provide an adequate and reasonably uniform test of efficiency, only those cases (treated or untreated) have been included in this analysis in which the presence of marked toxæmia, accompanying other signs and symptoms of gas gangrene, was recorded by the clinician. Since bacteriological confirmation of the diagnosis was, for obvious reasons, not always attainable, the possibility that some cases were due to streptococcal infections (MacLennan, 1943a) is not excluded. The figures in the ensuing paragraphs refer to the toxic cases on which the analysis was finally made.

The evaluation of a single therapeutic measure in gas gangrene is complicated by many variables, particularly in field conditions. First, there are the factors which may determine whether treatment as a whole is effective: these include the interval between the onset of the disease and treatment, in relation to the rate of development after onset; the site of the wound and the general condition of the patient; the nature of the pathogenic clostridia present, and of concomitant infections; the facilities for surgery and nursing. So far as is possible with the data available, these factors will be taken into account by grouping similar cases together and analysing the groups separately. Secondly, since the treatment advised consists of two measures—the use of surgery, to which the employment of drugs is ancillary, and the use of antitoxin—it is necessary to evaluate both measures. Thirdly, it is necessary to know whether there has been any selection of cases for treatment.

It may be useful to discuss here the general aspects of the probabilities with regard to the effectiveness and the practice of the two main lines of treatment. The necessity for speedy and adequate surgical treatment of patients with established gas gangrene is well recognized and has been repeatedly urged. The patients in whom gas gangrene developed formed a very small proportion of the total number of wounded, and were under the care of surgical specialists; the high general level of skill and care afforded can be gauged from the very low general fatality rate of patients with limb injuries—that is, with wounds of a type prone to develop gas gangrene (Pulvertaft, 1943). As might be expected, appropriate surgical measures were recorded in the majority (86%) of the reports

* A report to the War Wounds Committee of the Medical Research Council.

† Therapeutic dose: 7,500 i.u. *Cl. welchii* antitoxin; 3,750 i.u. *Cl. septicum* antitoxin; 2,500 i.u. *Cl. oedematiens* antitoxin; 20% in excess in each ampoule=16,500 units polyvalent antitoxin.

here analysed; the only reasons given for the omission of such measures were that the patient was too ill for operation and that gas gangrene was not diagnosed before death. For the present object it is not necessary—and certainly not within my competence—to criticize the surgical treatment in an individual patient; but the time of intervention and its effectiveness as judged by the recurrence or otherwise of infection after amputation have been considered.

The position with regard to the use of antitoxin was different, since its therapeutic value was not fully established. It might be suspected that its early and energetic use would be prompted largely by personal faith, and that its use at a later stage would often be due to a last hope of saving life. It has been realized that many were unfamiliar with the theory and practice of antitoxin therapy. It is a recognized principle that if antitoxin is given at an early stage of an infection by toxigenic bacteria it will be more effective in saving life than if it is given later, and that the amount of antitoxin needed for an individual patient cannot be arbitrarily prescribed. Though antitoxin was given to the majority (82%) of the patients, little more than half of them received it promptly or by intravenous injection, and frequently the dose was not repeated. The time of administration of gas-gangrene antitoxin is indeed a factor in determining its effectiveness; it is therefore very important to know whether the patients treated promptly with antitoxin were selected because they were less severe cases, since these might respond better to any form of treatment. The total amount of antitoxin given is also a factor, but a statistical analysis of the relative effect of different amounts of polyvalent antitoxin would require full bacteriological data, which are not yet available. It should therefore be emphasized that the main object of the present analysis was to find out whether antitoxin was of any value in treatment, by comparison of the fatality rates of the treated and untreated cases; the extent of this value is dependent on a number of factors, including, no doubt, the size of the dose of antitoxin.

Throughout this report a difference is regarded as significant if it exceeds twice its standard error, in which case it would occur by chance less than 5 times in 100 trials. If two groups differently treated show a "significant" difference of fatality the result does not prove, in the colloquial sense of the word, that the difference was due to the method of treatment, but it is reasonable to suppose so unless it can be shown that the groups were differentiated also in some other way.

Reports on Anaerobic Wound Infection

The reports received on cases of anaerobic wound infection fell into three series, excluding 6 in which the necessary data for tabulation were lacking:

Series I.—88 reports on casualties in the B.E.F. in May and June, 1940, returned on Army Form I 1241 (Dunkirk cases). In many of these reports the data recorded were not sufficient for the differentiation of toxic and mild cases, nor was it possible to distinguish casualties wounded in battle in Flanders from those wounded on the beaches. The entire series has been omitted from the analysis because the criterion for inclusion could not be applied; from other information available it seems probable that many of these cases were not examples of true gas gangrene, but rather of lesser forms of anaerobic wound infection.

Series II.—85 reports on casualties in the M.E.F. from 1940 to 1943. Most of these reports were considered by MacLennan (1943b) together with information on additional cases which had not been reported on Army Form I 1241. To avoid confusion this series has been omitted from the analysis, but the data obtained by MacLennan are quoted. The outstanding features of this series of cases were wounding in the desert, delay in treatment, with a high proportion of cases established on admission, and the frequent incidence of *C. oedematis* infection.

Series III.—165 reports of anaerobic wound infections from other theatres of war, returned on Army Form I 1241 and its supplement between Aug., 1940, and June, 1943. In the supplement clinicians were asked to report the presence and degree of general toxæmia. The criterion of gas gangrene taken for inclusion of a case in this analysis—the presence of marked toxæmia—was noted in 139 cases (85%). Three others were reported as "anaerobic wound infection without gas gangrene." Of the remaining 23 patients, 5 received prophylactic and therapeutic doses of antitoxin, 10 received a therapeutic dose, and 8 received no antitoxin; all these 23 subjects made satisfactory progress with, in general, the minimum of operative intervention, and in the absence (or non-recording) of marked

toxæmia it was doubtful if they could be included as "survivors from gas gangrene," either in the treated or in the untreated group.

The patients in Series III were grouped first according to Service, etc., and to the circumstances of wounding:

- 38 civilian air-raid casualties.
- 42 Army casualties treated in this country. In most of these patients the wounds were similar to battle wounds—i.e., caused by trench mortars, splinters, and bullets—and appear to have been sustained in accidents.
- 11 R.A.F. casualties treated in this country. There is no evidence that any of these patients was wounded during an operational flight.
- 17 casualties from the Royal and Allied Navies and Merchant Navies. These were scattered cases treated variously in this country, in hospital ships, and in medical units of the M.E.F. and B.N.A.F.
- 52 casualties from British, Allied, and enemy land and air Forces, treated in medical units of the B.N.A.F. between Oct., 1942, and May, 1943.
- 5 casualties in the Army over-seas.

Some particulars of the groups in Series III are shown in Tables I and II.

TABLE I

Group of Series III	Total Cases	Toxic Cases	Dths.	Fatality (% of Total Cases)	Amputations (% of Total Cases)	Transfusions or Infusions (% of Total Cases)
Civilian	38	32	20	52.6	50.0	58.0
Army U.K. .. .	42	34	17	40.4	54.8	54.7
R.A.F. U.K. .. .	11	11	7	63.6	36.4	54.5
Naval and seamen ..	17	16	9	52.9	29.4	68.8
B.N.A.F. .. .	52	43	25	48.1	50.0	63.5
Army over-seas ..	5	3	1	20.0	20.0	80.0
Total	165	139	79	47.9	47.3	60.0

TABLE II

Group of Series III	Toxic Cases	Estab. on Admission	No Antitoxin		With Antitoxin		
			Cases	Dths.	Cases	% of Total	Dths.
Civilian	32	6	5	5	27	84.5	15
Army U.K. .. .	34	4	3	3	31	91.5	14
R.A.F. U.K. .. .	11	0	2	2	9	81.8	5
Naval and seamen ..	16	7	4	3	12	75.0	6
B.N.A.F. .. .	43	21	11	8	32	74.5	17
Army over-seas ..	3	1	0	0	3	100.0	1
Total	139	39	25	21	114	82.0	58
Mean fatality rate			84.0%		59.9%		
			Difference = 33.1 = 10.9 Diff. S.E. = 3.3				

As might be expected from the difficulties of collection and transport, the proportion of the cases of gas gangrene in which the disease was already established on admission to hospital is much higher among the casualties wounded in battle—and in the few cases among those wounded at sea—than among those wounded in this country. The proportions of toxic cases, amputations, transfusions, and deaths, and the proportions of the total number of toxic cases treated with antitoxin, are not, however, significantly different in the different groups. It will be seen from Table II that the mean fatality rate for all the patients who received antitoxin is significantly less than for those who did not receive it. Moreover, the fatality rate of the treated patients is lower in each of the constituent groups, in spite of gross differences between these various groups in the circumstances of wounding—such as the nature of the soil and climate, the cause of injury, and the physique of the patients—and in the general facilities for treatment of casualties. It has been considered permissible, therefore, since the numbers in each group are too small for further subdivision, to take the series as a whole and regroup the cases according to the time and nature of treatment and the nature of the wound.

The cases have been graded according to the time of administration of antitoxin as follows: (a) initial dose given within 6 hours of diagnosis; (b) initial dose from 6 to 24 hours after diagnosis; (c) initial dose more than 24 hours after diagnosis. Owing to lack of detail in some reports it is not possible to distinguish between intravenous and intramuscular injection, but at least 40% of the cases in the first category received the initial dose intravenously: the initial doses ranged from 4,000

units intravenously at the time of diagnosis to 40,000 units intramuscularly. The time of administration was not always given explicitly; in the few instances in which it was not clear from the context that the dose had been given within 6 hours the case was placed in the 6-24 hour category.

Effect of Delay in Treatment

Treatment should properly be judged in relation to the time of onset of the disease, but in practice this is impossible, as the time of onset even in cases developing in hospital was often not known within several hours; generally the time noted was the time of diagnosis. When the patient was admitted with established gas gangrene, only the maximum possible interval between onset and diagnosis could be gauged from the time of wounding.

TABLE III

Antitoxin Therapy	Onset in Hospital			Established on Admission		
	Cases	Dths.	Fatality	Cases	Dths.	Fatality
Nil ..	19	17	89.5	6	4	66.7
24 hours after diagnosis ..	8	5	62.5	1	1	100.0
6 to 24 hrs. " " ..	22	19	86.4	7	4	57.2
0 to 6 " " " ..	51	22	43.0	25	7	28.0
Total ..	100	63	63.0	39	16	41.0

It might well be expected that the interval between onset and treatment would be so much longer in the cases already established on admission to hospital that treatment with antitoxin would be too late to be effective, and the fatality rate therefore higher than that of comparable cases developing in hospital. In Table III, however, no significant difference can be demonstrated between the fatality rates for the corresponding category of antitoxin therapy in the two groups. It could no doubt easily happen that the disease might develop in some patients during evacuation, only an hour or so before their arrival and examination at the hospital, so that they received treatment more promptly than others, already in hospital, in whom the disease developed more insidiously. Be that as it may, it appears probable that there was no material difference between these two groups in the range of time between onset and diagnosis, and that there is therefore no necessity to analyse the groups separately with respect to other factors. It will be realized that this is a finding particular to this series of cases, in which the majority of the gas-gangrene infections established on admission occurred in a single campaign; in different circumstances the patients in whom the disease developed during evacuation might be received too late for treatment to be effective.

Selection of Cases for Treatment

It was previously mentioned that it was necessary to know if the patients treated early with antitoxin were selected because they were less severe cases who would have responded better to any treatment. One test of the relative severity of the cases is to compare treated and untreated groups at the time of diagnosis to ascertain the proportion of rapidly fatal cases in each group. Table IV shows the numbers and proportions of the patients in each group dying at different intervals after diagnosis.

TABLE IV

Time of Death after Diagnosis	No Antitoxin		Antitoxin after 24 hrs.		Antitoxin 6 to 24 hrs.		Antitoxin 0 to 6 hrs.	
	Deaths		Deaths		Deaths		Deaths	
	No.	%	No.	%	No.	%	No.	%
0 to 6 hrs. ..	2	8.0	0	0	0	0	1	1.3
6 to 12 hrs. ..	5	20.0	0	0	5	17.2	8	10.5
12 to 24 hrs. ..	5	20.0	0	0	7	24.1	5	6.6
24 to 48 hrs. ..	3	12.0	0	0	5	17.2	6	7.9
2 to 4 days ..	4	16.0	4	44.4	5	17.2	6	7.9
Over 4 days ..	2	8.0	2	22.2	1	4.5	3	4.0
Total deaths ..	21	84.0	6	66.7	23	80.2	29	38.2
Total cases ..	25		9		29		76	

Of 34 patients who did not receive antitoxin within 24 hours, 7 (20%) died within 12 hours of diagnosis, while of 76 who received antitoxin within 6 hours, 9 (11.8%) died within 12 hours. The proportions are not significantly different, and

it is assumed that antitoxin has not already affected the fatality rate. Moreover, of the group who received no antitoxin within 24 hours more than half lived for more than 24 hours. It may be noted also that there was ample time for treatment to be given, whether or not it was effective: only 3 patients died within 6 hours of diagnosis. The group given antitoxin between 6 and 24 hours after diagnosis has not been taken into consideration, as times of administration and death were not noted exactly enough. It appears that the group treated early with antitoxin contained a fair proportion of rapidly fatal cases, and that the group not treated contained a high proportion of cases which were comparatively slowly fatal. This is therefore no evidence of a selection of the less severe cases for early treatment with antitoxin.

Fatality Rate in Various Categories

The time of diagnosis in the hospital at which treatment was carried out has been taken as the base-line in grading the time of the initial dose of antitoxin and the time of surgical intervention. Table V shows the data relevant to the effect of surgical treatment and antitoxin on the fatality rates of the toxic cases and of two categories separated approximately according to the site of the gas gangrene as "thigh" cases (thigh, buttock, and abdomen) and other cases (leg, arm, and other sites).

TABLE V

Therapy	"Thigh" Cases			Other Cases			All Cases		
	Cases	Deaths		Cases	Deaths		Cases	Deaths	
		No.	%		No.	%		No.	%
Surgery nil; antitoxin nil	6	6	100.0	1	1	100.0	7	7	100.0
Surgery nil; antitoxin plus	11	10	91.0	2	2	100.0	13	12	92.4
Surgery plus; antitoxin nil	12	8	66.7	6	6	100.0	18	14	77.8
Surgery plus; antitoxin after 24 hrs.	2	1	33.4	4	2	50.0	6	3	50.0
Surgery plus; antitoxin 6 to 24 hrs.	11	11	100.0	13	7	53.7	24	18	75.0
Surgery plus; antitoxin 0 to 6 hrs.	29	16	55.0	42	9	21.4	71	25	35.2
Total ..	71	52	72.2	68	27	39.7	139	79	56.8

Table VI shows the fatality rates, according to the time of amputation and the time of the initial dose of antitoxin, in the 69 patients who underwent amputation for the treatment of gas gangrene.

TABLE VI

Antitoxin Therapy	Amputation 0 to 6 hrs.			Amputation after 6 hrs.			All Cases		
	Cases	Deaths		Cases	Deaths		Cases	Deaths	
		No.	%		No.	%		No.	%
None ..	4	3	75.0	8	7	87.5	12	10	83.4
After 24 hrs. ..	0	0	0	4	1	25.0	4	1	25.0
6 to 24 hrs. ..	5	5	100.0	7	3	42.8	12	8	66.7
0 to 6 hrs. ..	28	10	35.8	13	4	30.8	41	14	34.2
Total ..	37	18	48.6	32	15	47.0	69	33	47.6

Amputation was the first major surgical measure recorded in 64 of these cases; in 5 patients it was carried out after excision had failed to control the infection. Recurrence of gas gangrene in the stump was noted in only two patients, so that this group is substantially one in which the infection was eliminated at a definite time.

From the data in Tables V and VI the following points emerge:

Fatality Rate of Untreated Cases

There are three groups of patients who did not receive the composite treatment recommended—namely, those who had no surgical treatment and no antitoxin, those who had antitoxin but no surgical treatment, and those who had surgical treatment but no antitoxin; the fatality rate is not significantly different in the three groups. These groups comprise 29 cases, with 24 deaths, in which the site of gas gangrene involved the thigh, buttock, or abdomen; and 9 fatal cases in which the gangrene involved the leg, arm, or other sites. The mean fatality rate (87%) emphasizes the remorseless nature of the disease, and

ne data—so far as they go—suggest that when treatment is lacking or inadequate the site of the infection makes no inference to the issue.

Effect of Antitoxin in Patients receiving Surgical Treatment

The mean fatality rate of all the patients who received both antitoxin and surgical treatment (Table V, last column) is 5.5%. This rate is significantly lower (41.3 ± 9.4) than that of the mean rate of those who did not receive the combined treatment. This result would probably occur by chance less than once in 1,000 trials. A similar effect of antitoxin is seen in the group of patients in whom the spread of infection was controlled by amputation (Table VI, last column), the mean fatality rate of the treated group (40.4%) being again significantly lower than that of the group who did not receive antitoxin. It seems clear that the combined use of surgery and antitoxin was a more effective method of treatment than either of those measures alone.

Time of Administration of Antitoxin

Considering the fatality rates for all types of cases (Table V, last column), it will be seen that the decrease on treatment with antitoxin is due almost entirely to the decrease in the group treated within 6 hours of diagnosis, as the rates for patients treated later are not significantly different from those for the untreated group. In a comparison of the fatality rates of different groups of patients who all received antitoxin, the total amount of antitoxin given and the identity of the infecting organism should be taken into account, and not merely the time of the initial dose. The distribution of the total dosage given to those patients who also received surgical treatment is shown in Table VII, the patients being grouped according to the site of the infection and the time of the initial dose of antitoxin.

TABLE VII

Time of initial dose:	Group A				Group B			
	0 to 6 hours				6 to 24 hours			
Subgroup:	1		2		1		2	
Site of infection:	"Thigh" Cases		Other Cases		"Thigh" Cases		Other Cases	
Total Dose of Poly-valent Antitoxin	No.	Dths.	No.	Dths.	No.	Dths.	No.	Dths.
Units:								
Up to 20,000	6	2	18	6	3	3	8	5
20,000 to 50,000	12	8	12	2	6	6	4	1
50,000 to 100,000	5	3	7	1	0	0	1	1
Over 100,000	6	3	5	0	2	2	0	0
Total	29	16	42	9	11	11	13	7
Fatality rates	35.2%				75.0%			

It is not possible to draw any definite conclusion from the figures in Table VII, since, apart from the fact that the numbers are small, the necessary bacteriological data are not available. Nevertheless there are some tendencies which are of interest.

First, with an early initial dose and the same total dose of antitoxin, the fatality rate of the "thigh" cases tends to be higher than that of the other cases; if the patients are grouped as receiving up to or over 50,000 units of antitoxin the difference between the two types of case is quite significant arithmetically. MacLennan (1943b), in noting the distribution of the different sites of infection in his series of cases, gives figures which show that the mean fatality rate of all the thigh, buttock, and abdominal cases was 68%, and of all those involving the arm or leg 37.6%; these figures are closely similar to those given in Table V for the present series of cases (72.2 and 39.7%). The poorer response to treatment when the gas gangrene involves the thigh and buttock region appears to be a general experience, and it is probably attributable to the difficulties of surgical excision and to the anatomical factors affecting the blood supply of these sites.

Secondly, Table VII shows that there is a tendency for the fatality rate to be higher when a dose of a certain size—e.g., 20,000 units—was given later than when it was given early. This, of course, is consistent with both the theory and the results of experimental work—that an amount of antitoxin sufficient to neutralize all the toxin present will be effective in saving life if given at an early stage, when the damage done by the toxin is minimal, and ineffective if given later, when the damage is irreparable.

Thirdly, it will be seen that in the subgroup A2, in which all the patients received the initial dose of antitoxin within 6 hours, the fatality rate tends to fall as the total dose rises from 20,000 to 50,000 units or more. Moreover, of all the patients receiving antitoxin early (Group A), 32.4% received a total dose of more than 50,000 units of antitoxin, compared with only 12.5% of those (Group B) who received the initial dose late; it appears probable that the striking difference in the fatality rates is due not only to the fact that the one group received antitoxin more promptly than the other, but also to the fact that this group received larger doses, though, as has been said, the data are not sufficient for statistical treatment. That there is a possible fallacy in this tentative conclusion has been pointed out by Prof. M. Greenwood: thus, one cannot be certain that the fatality was lower because the larger dosage of antitoxin was given and not that the larger dosage was given because the fatality was lower—i.e., the patients in this group lived long enough to receive the larger dosage. For that reason any conclusion from these data as to the value of the high doses of antitoxin can only be provisional.

Time of Surgical Intervention

Surgical operations of a major nature were carried out within 6 hours of diagnosis in 68 of the 120 patients treated, within 12 hours in 81, and within 24 hours in 98 (81.6%). It seems clear, however, that even rapid elimination of the whole site of infection is not by itself a sufficient treatment in a toxic case; the fatality rate for patients who underwent amputation within 6 hours of diagnosis without having received antitoxin (Table VI) is not significantly different from 100%, while for those who received antitoxin within this time the rate is significantly less. Most of the patients who were treated early with antitoxin received the dose pre-operatively or at the time of operation; this is perhaps worthy of consideration, since in 11 of the 60 fatal cases in which surgical treatment was carried out death took place during or within two hours of operation.

Effect of Sulphonamide Drugs

MacLennan (1943b) showed that in his series of cases in the M.E.F. the striking reduction in the fatality rate of the group treated with antitoxin was independent of treatment with sulphonamide drugs; his figures are reproduced in Table VIII.

TABLE VIII (From MacLennan, 1943b)

Drug Therapy	No Antitoxin		With Antitoxin		Difference
	Cases	Deaths	Cases	Deaths	
With sulphonamides	28	22 (78.6%)	58	19 (32.8%)	35.8 ± 11.5
No sulphonamides	19	15 (78.9%)	8	2 (25.0%)	53.9 ± 20.3

In the present series more than 90% of the patients had received sulphonamide drugs, and the numbers untreated with drugs were so small that it was not possible to find out from the records whether the combined use of surgery, sulphonamide drugs, and antitoxin was more effective than surgery and antitoxin by themselves. It should be emphasized that several varieties of sulphonamide drugs and regimes were employed, and this necessarily complicates any attempt to assess the results. All that can be said under this heading is that the relevant data (Table IX) are not sufficient to provide significant statistical evidence of a beneficial effect of the drugs.

TABLE IX

Therapy	"Thigh" Cases		Other Cases	
	No.	Deaths	No.	Deaths
Surgery; antitoxin 0-6 hrs.: With sulphonamides	28	15 (53.6%)	41	8 (19.5%)
No sulphonamides	1	1 (100.0%)	1	1 (100.0%)
Surgery; antitoxin late or nil: With sulphonamides	23	18 (68.3%)	22	14 (63.6%)
No sulphonamides	2	2 (100.0%)	1	1 (100.0%)
No surgery; antitoxin 0-6 hrs.: With sulphonamides	3	2 (66.7%)	1	1 (100.0%)
No sulphonamides	1	1 (100.0%)	0	—

Effect of Complications; Serum Reactions

The opinion was recorded by the clinician in 14 reports that death was due not solely to gas gangrene but to complicating factors. After making an initial recovery, 2 patients died from secondary hæmorrhage and 1 from pulmonary embolism. The

omission of these 17 cases from the appropriate categories makes no difference to the general trend of the results.

Serum reactions were noted in only 3 of the 114 patients in the series treated with antitoxin; these occurred after some hours or days in the form of a rash or pyrexia, and apparently gave no cause for anxiety.

General Remarks

The reduction of the fatality rate in the group receiving both surgical treatment and antitoxin can be reasonably held to establish the value of antitoxin in the treatment of gas gangrene. It is to be hoped that with a more effective use of antitoxin the fatality rate of 45% for treated cases will fall considerably. Speed in the administration of antitoxin is clearly essential for good results, but it is no less important that the amount of antitoxin given should be adequate for the individual case, since the neutralization of toxin by antitoxin is a quantitative reaction. It has been recently recommended (*M.R.C. War Memorandum No. 2*, revised second edition, 1943) that the initial therapeutic dose of polyvalent antitoxin should be not less than 50,000 units; the figures in Table VII indicate that, though often enough such a dose may be more than ample, it is not excessive as a routine.

The clinician still has the onus of judging quickly whether the dose given has been sufficient to neutralize all the toxin—that is to say, whether a previously rapidly progressive toxæmia has been arrested—or whether the dose of antitoxin has been insufficient and the progress of toxæmia is still acute. Delay in the neutralization of the toxin present cannot be compensated by giving an excess of antitoxin at a late stage; on the other hand, since the individual capacity to recover from the effects of toxæmia is incalculable, there is no justification for withholding an adequate dose of antitoxin from a patient received late for treatment, however small the chance of recovery may be. In the treatment of gas gangrene the probability should be borne in mind that the amount of toxin present in the body is increasing so long as the infection is spreading in the affected tissue. A patient received late for treatment, or one in whom surgical and chemotherapeutic measures have not been completely effective in eradicating the infection, may therefore need heroic or repeated doses of antitoxin, not because an excess has at any time a beneficial effect, but because an amount equivalent to the toxin present is the dose justifying a hope of recovery. This is entirely different from deprecating the continued administration of large doses of antitoxin to a patient in whom the infection has been controlled and the effects of the toxæmia are already vanishing.

Patients in whom the site of gas gangrene involved the thigh, buttock, or abdomen showed a poorer response to doses of antitoxin of the order recommended than those in whom the site was more favourable to the elimination of the infection either by the surgeon and by Nature. These findings support the recommendation that surgical treatment should be supplemented by chemotherapeutic measures as well as by antitoxin therapy, and point to the need for local chemotherapeutic agents more effective against clostridia than the sulphonamide drugs in use.

Summary

The value of antitoxin in the treatment of established gas gangrene has been examined in a series of 139 cases in which the patients were suffering from toxæmia to a marked degree. The fatality rate was significantly lower among the patients who received antitoxin, and this difference between treated and untreated cases persisted in those who received major surgical treatment, including a group in whom the site of primary infection was rapidly extirpated by amputation. The combined use of surgery and antitoxin was therefore more effective than that of surgery alone.

The effect of antitoxin was more pronounced in those who received the initial therapeutic dose soon after diagnosis, but this difference was probably due not only to the speed of administration but also to the fact that a greater proportion of the patients in this group received a large total dosage (50,000 units or more) of antitoxin.

The fatality rate of the patients who received no major surgical treatment was nearly 100%, and in the cases reported here the rate in this group was not reduced by antitoxin therapy. Patients in whom the site of the gas gangrene involved the thigh, buttock, or abdomen showed a poorer response to doses of antitoxin of the

order recommended than those in whom the site was more favourable to the elimination of the infection.

These results emphasize the necessity for the early and combined use of surgery, effective chemotherapy, and antitoxin in the treatment of gas gangrene.

This evaluation of antitoxin in the treatment of gas gangrene has been made possible by the work of the medical officers reported their cases, often in difficult conditions. Thanks are due to the Medical Directors-General of the three fighting Services, the E.M.S. for making the case records available for analysis, greatly indebted to Prof. M. Greenwood and Dr. E. Lewis-Francis for their constructive criticism and for the verification of the significance of the data; to Mr. C. H. S. Frankau for his advice on clinical aspects; to Dr. F. H. K. Green for his help in preparing this report; and to Lieut.-Col. H. J. Bensted for much useful information. It is a pleasure also to thank Major-Gen. L. T. I and the members of the Anaerobic Wound Infection Subcommittee for their criticism and many illuminating discussions.

DYSPEPSIA: AN INVESTIGATION

BY

HAROLD EDWARDS, M.S., F.R.C.S.

Brigadier, A.M.S.

AND

W. S. C. COPEMAN, M.D., F.R.C.P.

Lieut.-Col., R.A.M.C.

The enrolment into the Forces of most of the young manhood of the country has presented us with an opportunity for statistical investigation of some of the commoner ailments. The immediate demands of warfare are so far uppermost that the clerical assistance necessary for statistical research cannot be spared. Thus little can be done towards elucidating the medical problems which in civilian life were so urgent and which we shall have to face again in the years of peace. One of the most important of these problems from a sociological and industrial standpoint is dyspepsia. In the years preceding the war the project of a research centre for gastric disorders was very much before the mind—a centre whose sole object was research into the causation of these disorders. The clinical, radiological, biochemical, and sociological data were to be collected and collated, and submitted to statistical analysis.

An opportunity of doing something along such lines presented itself at a military hospital. A scheme was devised and put into practice which had a twofold object: (1) to make some contribution to the immediate problem of dyspepsia among the troops the hospital served; (2) to furnish data for statistical research. A "gastric board" was formed consisting of the officers in charge of the medical and surgical divisions, the medical specialist, the radiologist, the pathologist, the psychiatrist, and a general-duty officer.

All dyspeptics were admitted into a 30-bed ward for investigation. None was treated there—an important point, and a partial answer to the criticism levelled against the segregation of dyspeptics. The general-duty officer examined each patient on admission, and took the history according to an agreed schedule. The whole worth of the scheme depends upon the way this part of the work is done, and it requires for its performance a medical officer of ability who is really interested in the problem. In the present instance we were fortunate in having the services of Captain (Miss) Phoebe Charlton, who, except during brief periods of leave, was responsible for all the histories taken. Within five days of admission each patient was x-rayed (Major Baird; later Major Wearing), and test-meal and occult-blood examination were done (Major Roper; later Major Stewart). The board met weekly, and saw and discussed each case, and decided upon disposal. If indicated gastroscopy was performed. Cases

which there was no evidence of organic disease or in which there seemed to be a psychological background were sent for interview with the psychiatrist (Major Barber; later Lieut., now Major, Stungo). It was the duty of the medical specialist (Major Slot; later Major Cherniack) to examine each patient from the general standpoint, and to prevent the board from falling into the error of attributing all symptoms to the stomach or duodenum.

After 12 months, during which 436 patients were seen, the data were collected and submitted for analysis. Through the agency of Lord Dawson of Penn, Mr. W.J. Martin, of the Division of Epidemiology and Vital Statistics of the London School of Hygiene and Tropical Medicine, paid a brief visit to the hospital and took away the case sheets for analysis. The policy of having the analysis made by a disinterested and unbiased worker was deliberate. It resulted, however, in certain unforeseen disadvantages—for example, the "lumping" together of gastric and duodenal ulcers, and difficulty in interpreting the data on gastric analysis (which for this reason has been omitted from Mr. Martin's report). It is now realized that a closer liaison between clinician and statistician would have been an advantage.

For reasons of space it is not proposed to publish the actual figures furnished by the statistician, excepting one table as a specimen; we shall confine ourselves to quoting the headings and a statement of what the figures tended to show. Unfortunately, it was impossible to obtain data from a similar age group of non-dyspeptics to act as a control.

Analysis of Cases

There were 436 cases in all. These were divided into two groups—139 ulcer and 217 non-ulcer cases. The remaining 80 cases were not included in the statistical analysis; in 65 no diagnosis had been made, as evacuation interrupted investigation, and in 15 the symptoms were thought to be due to a lesion other than one affecting the stomach or duodenum.

The Ulcer Group.—We accepted the following criteria in making the diagnosis of ulcer: (1) the presence of an ulcer crater in the radiograph; (2) a typical clinical history, with high acidity and positive occult blood (even if the radiological diagnosis was doubtful or negative); (3) a previous history of perforation; (4) visual evidence at gastroscopy—this, of course, only in the case of gastric ulcer.

The Non-ulcer Group.—In this group were placed all cases complaining of dyspeptic symptoms in which there was no radiological evidence of an ulcer and in which the clinical evidence of ulcer was insufficient. Most of the cases were gastroscopied. The 217 cases are made up as follows:

No physical disease detected (functional dyspepsia)	180
Gastritis (diagnosed at gastroscopy)	23
*Duodenitis or duodenal enteritis	9
Gastro-enterostomy	3
Pyloric spasm	1
Hypersecretion and hyperchlorhydria	1

*Radiological diagnosis.

It is probable that some of the cases in the non-ulcer group actually had a duodenal ulcer. For instance, in one case an operation for perforated duodenal ulcer was performed at another hospital within a week of discharge. It is thought unlikely that many cases of ulceration were overlooked, however, though it must be admitted that the influence of pending medical boards was felt considerably, for few of them are prepared to accept a diagnosis of duodenal ulcer unless there is definite radiological evidence of it. There is no doubt that the frailties of radiological diagnosis of duodenal ulcer are not sufficiently recognized.

Findings

1. **Civilian Occupations.**—No difference in the two groups (ulcer and non-ulcer) was found relating to occupation except in the case of miners, in whom the percentage in the ulcer group was 2.9 (4 out of 139) and in the non-ulcer group 7.4 (16 out of 210). There is thus a suggestion that miners may be subject to a type of dyspepsia in which localized ulceration does not occur.

2. **Marital State.**—The incidence of both ulcer and non-ulcer dyspepsia appears to be equal in single and childless married

men. Ulcer dyspepsia is, however, relatively more common than non-ulcer dyspepsia in men with two or more children. This is probably due to the fact that the mature married man is less likely to seek treatment unless he has definite cause.

3. **Rank.**—Private soldiers in the non-ulcer group numbered nearly twice those in the ulcer group (172 : 98), whereas there were rather more N.C.O.s (lance-corporals, corporals, and sergeants) with an ulcer than those without (38 : 34). There are two explanations for this: (a) the selection of the best types for promotion; (b) responsibility diminishes the tendency to report sick without adequate cause.

4. **War Service.**—One-third of the cases in each group were Regulars or Reservists and two-thirds were war enlistments. In about one-third of the cases in both groups (ulcer and non-ulcer) the symptoms began during civilian life. There is thus no evidence that Army service has any influence upon the development of non-ulcer dyspepsia as opposed to ulcer dyspepsia. This is a point of interest, for it suggests that functional dyspepsia is as common, relative to organic dyspepsia, in civilian as it is in Army life. It is possible, indeed probable, that more use is made of it in Army life in order to evade the performance of duties.

5. **Family History of Dyspepsia.**—As expected, this is common, and occurs almost equally in both groups (ulcer in 57% and non-ulcer in 54.3%).

6. **Duration of Symptoms.**—There was no difference between the two groups in the duration of symptoms, which averaged six years. Both the age at onset of symptoms and, it follows, the age when seen were earlier in the non-ulcer group.

7. **Habits.**—There were few heavy drinkers and few teetotallers—most drank beer in moderation. Likewise with smoking. The largest group was in fact composed of those who drank and smoked moderately—61.6% of the ulcer patients and 61.2% of the non-ulcer patients. This does not suggest that smoking and drinking are not a factor in the cause of dyspepsia—a comparison of non-dyspeptic cases would be of especial value here—but that whatever part these habits may play is equal in both ulcer and non-ulcer dyspepsia. In both groups two-thirds of the patients stated that their meals were regular.

8. **Symptoms.**—(a) **Pain in relation to food.**—The average interval between food and pain was much higher in the ulcer than in the non-ulcer group, and the presence of a considerable period of freedom after food is significant of ulceration. (b) **Nocturnal pain.**—This was significantly more common in the ulcer group, and emphasis is laid upon this. If the patient is awakened by pain an hour or two after falling asleep and the pain is alleviated by taking something by mouth the probability of an ulcer is high. (c) **Miscellaneous.**—There was no significant difference between the two groups in the following: appetite—good in 57% of ulcer and 55% of non-ulcer patients; nausea—present in 82% of ulcer and 85% of non-ulcer patients; vomiting—present in 71% of ulcer and 76% of non-ulcer patients; flatulence—present in 79% of ulcer and 82% of non-ulcer patients. It is a matter for some surprise that vomiting is so common a symptom of an uncomplicated ulcer. In most cases, however, it was only an occasional incident.

9. **Relation of Symptoms to Food and Alkalis.**—The findings here are significant, and the statistician's figures and remarks are given in full.

Reaction to Food and Alkalis

	Ulcer		Non-ulcer		Difference Ulcer/Non-ulcer
	No.	%	No.	%	
Food:					
Relieved by food	92	71.9	70	42.7	29.2 ± 5.9;
Not relieved	36	28.1	94	57.3	significant
Total	128		164		
Alkalis:					
Relieved by alkalis	99	77.3	101	61.6	15.7 ± 5.5;
Not relieved	29	22.7	63	38.4	significant
Total	128		164		

Difference between percentage relieved by alkalis and percentage relieved by food:

Patients with ulcers, 5.4 ± 5.4; not significant.
Patients without ulcers, 18.9 ± 5.5; significant

Distributions

	Ulcer			Non-ulcer		
	Alkalis			Alkalis		
	Relieved	Not Relieved	Total	Relieved	Not Relieved	Total
Food:						
Relieved ..	78	14	92	55	15	70
Not relieved ..	21	15	36	46	48	94
Total ..	99	29	128	101	63	164
	$\chi^2 = 8.8756$ $P = 0.01$			$\chi^2 = 13.6682$ $P = 0.01$		

Remarks by Statistician: The percentage of patients with ulcers who were relieved by food and alkalis is larger than in the group without ulcers. The percentage relieved by food is not significantly larger than the percentage relieved by food in the group with ulcers. In the group without ulcers the percentage relieved by alkalis was significantly greater than the percentage relieved by food. The χ^2 s show that there is a relation between food and alkalis; the numbers who reacted in a similar way to both food and alkalis were larger than would be the case if the reaction of food and alkalis were independent.

The findings are clear-cut:—In most ulcer cases the pain is relieved by both alkalis and food. In the non-ulcer cases food usually fails to relieve but alkalis usually do. These findings are of the greatest diagnostic importance.

10. *X-ray Diagnosis.*—It should be noted that the 9 "negative" cases of ulcer were those in which either the clinical evidence was sufficient for a diagnosis or, in cases of gastric ulcer radiologically negative, diagnosis was by gastroscopy. The two terms "duodenitis" and "duodenal enteritis" crept in because of a change of radiologist. They are, we believe, synonymous, though we put little faith in either diagnosis.

	Ulcer	Non-ulcer
Negative ..	9	169
Inconclusive ..	4	12
Ulcer ..	119	—
Gastritis ..	—	9
Hypertrophic gastritis ..	—	1

Cholecystitis ..	—	1
? Adenoma ..	1	—
Congestion ..	1	—
? Prepyloric ulcer ..	—	1
	136	208

11. *Gastroscopy and Radiography.*—The gastroscope should be regarded as complementary to radiological examination. Its chief value is in those cases in which the symptoms appear genuine but in which the radiograph is negative, and in cases in which the radiograph suggests a lesion of the stomach but is not conclusive. Twenty-three gastroscopies were done in the ulcer group and 86 in the non-ulcer group. Gastroscopy diagnosed a gastric ulcer on 3 occasions when the radiological diagnosis was in doubt. It diagnosed gastritis on 23 occasions. In these the radiograph was positive in 7 cases, doubtful in 6, and negative in 10. In 3 cases of gastro-enterostomy the radiograph showed a duodenal ulcer in 1 and a normal stoma in 2. Gastroscopy showed evidence of a stomal ulcer in 1 and of peristomal gastritis in 1, passing 1 as normal. The gastroscope is thus an invaluable addition to our means of diagnosis.

12. *Psychiatrist.*—Only selected cases were referred to the psychiatrist—2 of the ulcer group and 101 of the non-ulcer group. No abnormal psychological state was found in 36 (including one of the ulcer cases). Some evidence of a psychological background was found in the remaining 67, varying from an anxiety state (25 cases) to maladjustment to surroundings (1 case). No conclusions can be drawn from these findings without the psychiatrist's assessment of a similar numerical group with no gastric symptoms, apart from the fact that no one personality type was characteristic.

13. *Previous Operations.*—Of the ulcer cases 23 and of the non-ulcer cases 28 had had an operation upon the abdomen. Of the 23 ulcer operations 7 were for perforation. There was a very significant finding in that of the 51 cases with a history of operation 26 had been for chronic appendicitis. In each case the operation had been done to relieve the symptoms of dyspepsia. We have no means of telling how many "chronic appendices" are successfully removed for this purpose, but the present figures

suggest strongly that the diagnosis of chronic appendicitis made, and acted upon, too frequently.

14. *Disposal.*—It may be of some interest to include following details of disposal:

Disposal of 336 Cases

	Ulcer	Non-ulcer
Returned to unit ..	1	116
Returned to unit after period of treatment or convalescent home ..	—	—
Evacuated (convalescent home or hospital) for treatment or observation ..	2	11
Transferred to another unit or change of duties ..	1	—
Prolonged period of convalescent treatment ..	—	—
To be kept under observation and x-rayed in six months' time ..	1	—
Category B (minor disability) ..	—	—
Category C (home service only) ..	4	2
Category E (discharged from the Army) ..	119	2
	128	20

Summary of Findings

Of 356 cases completely investigated 139 were regarded as having a peptic ulcer. Of these, 16 were gastric and 121 duodenal. Of the remaining 217 cases, 37 had evidence of a gastric or duodenal lesion other than ulcer; in 180 no organic lesion was found and the condition was labelled "functional dyspepsia."

The more significant results of the statistical returns were:

(a) Ulcer was relatively more common than non-ulcer dyspepsia among N.C.O.s than among privates.

(b) There was a family history of dyspepsia in a little over the patients in both groups.

(c) Duration of freedom from pain after food was longer in ulcer than in the non-ulcer group.

(d) The pain is relieved by food in nearly three-quarters of ulcer dyspepsia cases, but in less than half of the non-dyspepsia cases.

(e) True nocturnal pain, alleviated by taking something by mouth, is a more pronounced feature of ulcer dyspepsia than of non-dyspepsia.

(f) Gastroscopy is an invaluable aid in diagnosis.

(g) Of 103 patients referred to the psychiatrist (only 2 had ulcers) evidence of a psychological background was found in 65%.

(h) 26 of the patients had been operated upon previously for chronic appendicitis without relief from their dyspeptic symptoms.

Commentary

How did the scheme serve the two objects for which it was intended?

As a help to the immediate problem of dyspepsia in the Army, it was a success. The special features were: (a) The formation of a team to represent various aspects of knowledge. (b) Admission of patients for investigation only. They were kept on normal diet unless this was contraindicated; very few cases were treated. Investigation was carried out expeditiously and on an organized plan. (c) Rapid decision as to disposal. The president of the medical board in making the final decision in cases recommended as Category E was helped materially by the fusion of all the expert opinion available.

As a method of research the project is sound, but in the way it was carried out there are defects, which this experience should enable us to correct in future. The two chief lessons are: (a) a medical statistician should be employed; (b) a constant control should be kept of healthy men in similar age groups.

Our thanks are due to Col. M. J. Williamson, M.C., late R.A.M.C., for permission to publish, to Lord Dawson for his interest and help, and to Mr. W. J. Martin for his masterly analysis of the data.

W. H. Gordon, F. B. Parker, jun., and S. Weiss (*Arch. intern. Med.* 1942, 70, 396) record their observations on three cases of gummatous aortitis in patients aged from 35 to 42. In the first case the gummatous process completely occluded the right coronary artery and partially occluded the left one. In the second, gummatous lesions were present also at the base of the aortic valve; and in the third an extensive gummatous process affected not only the aorta but the pulmonary artery. Symptoms of gummatous aortitis such as dyspnoea, orthopnoea, precordial distress, cardiac asthma, pulmonary oedema, and haemoptysis are present only where there is narrowing or occlusion of the coronary arteries.

THE BACTERIOLOGY OF BRAIN ABSCESS

BY
PEARLAN, M.B., B.Chir.
(Service)*

BY
ALLAN M. McFARLAN, M.B., B.Chir.
(Emergency Public Health Laboratory Service)*

This paper reports the bacteriological findings in 48 cases of brain abscess which had been referred to neurosurgical clinics. I am indebted to the surgeons of seven such clinics for sending specimens of pus and for providing data about their patients.

Details of the Cases

Sex and Age.—Of the 48 patients, 36 were male and 12 female. The ages of three were not stated; the ages of the remaining 45 ranged from 5 to 53 years, and the numbers in successive decades were 4, 8, 11, 13, 7, 2.

Site of Abscess.—Forty-two patients had a single abscess of the brain was affected in 27. Of the single more than one. The right side and left sides in 2. Of the left in 19, and both right and left in the frontal lobe, 5 in the occipital lobe, 3 were cerebellar, 18 were in the frontal and parietal lobes, 15 in the temporal lobe, and 1 in the parietal lobes. Abscesses were present in the frontal and parietal lobes, and in 2 cases in the parietal and temporal lobes, and in 2 cases in the parietal and temporal lobes.

Probable Source of Infection.—Ear disease was considered to be the source of infection in 18 cases, sinusitis in 7, lung disease in 7, trauma (penetrating injury) in 3. Staphylococcal septicemia each provided one case. In 4 cases the source of infection was unknown.

Clinical Course.—The duration of abscess symptoms was known in 47 cases; in 15 it was less than one month, in 6 between one and two months, in 10 between two and three months, in 4 more than three months, in 4 years or more. Information about capsule formation was available for 39 cases. In 16 of them encapsulation was demonstrated histologically. In 7 of these cases there was a definite tough or firm wall was noted at operation. In 18 others a definite tough or firm wall was noted at operation. Of the 48 patients in whom observations indicated the absence of a capsule in 3 cases, in 15 others a definite tough or firm wall was noted at operation. Of the 48 patients in whom observations indicated the absence of a capsule in 3 cases, in 15 others a definite tough or firm wall was noted at operation. Of the 48 patients in whom observations indicated the absence of a capsule in 3 cases, in 15 others a definite tough or firm wall was noted at operation.

Technique and Results

Technique and Results

Films of the pus were stained by Gram and Ziehl-Neelsen methods. In all cases aerobic and anaerobic cultures were made on horse-blood agar plates and in ox-serum broth. When examination suggested the need for enriched or selective media, Fildes's agar, 20% ox-serum agar, or horse-blood agar with crystal violet (1 in 500,000) or sodium azide (1 in 1,000) were used.

TABLE 1.—Organisms found in 48 Brain Abscesses. (The Pus from One Abscess showed no Organisms in Films and Cultures were Sterile)

	Number of Times Each Organism Appeared		
	In Pure Culture (33 Cases)	With Other Organisms (14 Cases)	Total (47 Cases)
<i>Staph. aureus</i>	13	2	15
<i>Strep. pneumoniae</i>	6	4	10
<i>P. vulgaris</i>	4	1	5
<i>Strep. pyogenes</i>	2	9	11
<i>Strep. viridans</i>	1	8	9
<i>Non-haemolytic streptococci</i>	2	1	3
<i>Anaerobic streptococci</i>	1	2	3
<i>Unclassified streptococci</i>	1	—	1
<i>Pusiform bacilli</i>	1*	—	1
<i>M. tetragenus</i>	—	29	29
<i>Anaerobic diptheroids</i>	—	—	—
<i>H. influenzae</i>	33	—	33
Total number of organisms

- Seen in films only.

• Seen in films only.
† Two strains of fur.

Examination of films and cultures showed in 33 cases a single bacterial species (Table II), in 14 cases more than one species (Table II), and in one case no organisms. It is unlikely that delay in the post was responsible for any errors in the results concerned, as many were identical with those obtained at the clinic concerned. From some abscesses several specimens were examined and

* A report to the Medical Research Council.

the same organisms found on each occasion. Only in one traumatic abscess due to *Strep. pyogenes* did later specimens prove sterile. In budding the organisms the following points were noted. The three Type III strains were bile-soluble. The three Type III strains were anaerobic streptococci, and fusiform bacilli

[illegible]

Strep. pyogenes.—All four typed, one was Type 1, and one Type 2.

Strept. pyogenes.—The single strain gave a-lysis on horse-blood agar, and produced no soluble haemolysin. In primary cultures it was not bile-soluble, and produced no soluble haemolysin. In primary cultures it was not bile-soluble, and produced no soluble haemolysin. In primary cultures it was not bile-soluble, and produced no soluble haemolysin.

Non-haemolytic Streptococci.—Two strains grew on horse-blood agar horse-blood plates and no soluble haemolysin. In phosphate-buffered broth growth was more profuse anaerobically than aerobically.

Anaerobic Streptococci.—After 24 or 48 hours incubation at 37°C. as pin-point colonies obtained aerobically with liberal inoculum. No growth was obtained in serum broth. Four of these seven strains produced agar or in serum broth. Three other strains produced no precipitation with Group A, C, or G sera. Three other strains produced small coal-black colonies on horse-blood agar after 5 days' incubation. They were apparently similar in this respect to strains isolated by Colebrook and Hare (1933) from cases of puerperal fever.

Fusiform Bacilli.—These organisms appeared in pus films as long, thin, rod-shaped, Gram-negative bacilli, with some in pairs and some in chains. They were apparently similar to those described by Colebrook and Hare (1933) from cases of puerperal fever.

Fusiform bacilli.—These organisms were Gram-negative bacilli, slender fusiform or diphtheroid, Gram-negative. Many "ghost" cultures showed slender, beaded, Gram-negative bacilli; other cultures showed slender, beaded, Gram-negative bacilli; some cocci-bacilli and filaments. No growth was obtained after heating forms and irregular swellings. Three strains were killed by autoclaving at 60° C. for 30 minutes. The colonies on horse-blood agar plates after two days' anaerobic incubation were in most cases 1 mm. in diameter, round, smooth, and low convex; but a few strains had a diameter of 2 to 3 mm. diameter with a rough surface and gas, irregular edge. In serum sugars two strains produced acid and gas, one strain and salicin were not fermented. It seemed justifiable to place these organisms in the *Fusiformis* group, but not to assign them to any particular species in it, because individual strains shown Mannitol and organisms in the *Fusiformis* and some of *F. necrophorus* have these characteristics of *F. fusiformis* (Dack, 1940).

Aerobic Diphteroids.—Two strains of slender Gram-positive rods. On horse-blood agar plates they grew in the form of small, round, slightly raised, low convex colonies. The colonies were aerobic.

Anaerobic Diptheroids.—Two strains of slender Gram-positive bacilli seen in pus films grew only anaerobically. On horse-blood agar after two days' anaerobic incubation the colonies of one strain were 1 mm. in diameter, round, smooth, and convex; the colonies of the other were 2 mm. in diameter, irregularly circular, rough, flat, and sunken in the agar. Films from cultures showed Gram-positive diptheroid bacilli. No acid was produced in glucose, maltose, sucrose, or starch serum sugars.

the other were killed by the acid. No acid was produced by the diptheroid bacilli. No acid was produced by the sucrose, or starch serum sugars.

Micrococcus tetragenus.—An abundant growth of this organism was obtained from a specimen of pus which showed clusters of Gram-positive cocci in films. A similar result was obtained from another laboratory which had isolated *Srep. pyogenes* and *Staph. aureus* from specimens taken some months earlier when the abscess was first aspirated. The specimens from which *M. tetragenus* was isolated were obtained at the first aspiration of a recurrence.

Some of the strains isolated were used for the production of experimental brain abscesses in rabbits (Falconer, McFarlan, and Russell, 1943).

Most Common Organism in Brain Abscess

Of the 100 cases collected by other workers, 50 were studied here.

The Commonest Organism in Brain Abscess

The Commonest Organism in Brain Abscess

A comparison of the clinical data of cases collected by other authors (Evans, 1931; Atkinson, 1934) with those studied here showed that this series, though small, is a representative one. Analysis of the bacteriological findings in this series revealed no close association between the type of organism and the site of abscess or source of infection, so that the data as they stand are a fair sample for use in estimating the frequency with which various organisms are found in brain abscesses that are referred to neurosurgeon clinics. Rapidly fatal cases which do not reach the neurosurgeon might give different results.

Staphylococcus aureus was isolated from 15 of 48 cases. The age distribution of 11 of the cases from which *Staph. aureus* was isolated in pure culture was 1, 2, 3, 1, 4, 1 in successive decades. Thus the organism occurred in roughly one-third of the whole series and of each age group. "Streptococci" were seen in films or

Staphylococcus aureus was isolated from 15 of 48 cases. The age distribution of 11 of the cases from which *Staph. aureus* was isolated in pure culture was 1, 2, 3, 1, 4, 1 in successive decades. Thus the organism occurred in roughly one-third of the whole series and of each age group. "Streptococci" were seen in films on

isolated from 21 cases, but culture showed 10 strains to be anaerobic streptococci, 4 to be *Strep. pyogenes*, 2 *Strep. viridans*, and 2 non-haemolytic streptococci. Three strains were seen only in films. Thus, although "streptococci" were common, several species were represented. Fusiform bacilli were found in 10 cases; in 7 of these they were accompanied by streptococci of one species or another, and in one case by both streptococci and staphylococci.

The commonest organism, therefore, was *Staph. aureus*. Fusiform bacilli and anaerobic streptococci came next in order of frequency. *Strep. pneumoniae*, *P. vulgaris*, and *Strep. pyogenes* were also found in several cases.

Discussion

Although staphylococci were present in 15 of the 48 cases in this series and in 14 of 27 cases reported by Alpers (1939), other authors (Hasslauer, 1907; Lund, 1926; Atkinson, 1934) found them in only a few of their cases of brain abscess. It is difficult to account for this discrepancy. The predominance of staphylococci in the present series was not due to the inclusion of cases in infants, in which staphylococci are said to be very common (Sandford, 1928). Several authors have stated that streptococci are the commonest organisms, but the results of culture in this series suggest that several species of streptococci may have been represented. It is unjustifiable to group these species together and misleading to state that streptococci are the commonest organisms in brain abscess. Fusiform bacilli and anaerobic streptococci were often found, and on several occasions pneumococci grew only anaerobically in primary cultures. It is clear that anaerobic culture is an essential part of the examination of pus from brain abscesses.

It appears from Table I that more than one species of organism was present in a large proportion of the abscesses from which anaerobic organisms were isolated. Wámoscher and von Vársárhelyi (1933) showed that the injection of agar furnished a nidus in which tetanus spores could germinate, and it is possible that the use of agar in the inoculum was responsible for the production of abscesses in rabbits' brains with anaerobic streptococci and fusiform bacilli by Falconer *et al.* (1943). It seems therefore quite probable that brain abscesses due to anaerobic organisms originate in foci of lowered O-R potential (Fildes, 1927) produced by a vascular accident or by aerobic organisms which later die out.

In this series clinical evidence of encapsulation was obtained in 5 cases two months after the onset of symptoms, and in 8 cases with three months' history. Histological examination showed well-marked fibrous walls in 2 (pneumococcal) cases with six weeks' history, in 3 cases with two months' history, and in 6 cases with three months' history. However, the clinical observations concerned the superficial part of the abscess wall, where encapsulation is more rapid than in the parts nearer the ventricle (Northfield, 1942; Falconer *et al.*, 1943). Moreover, a deeper unencapsulated loculus was present in several abscesses which had apparently been present for six months or longer. It was therefore impossible to draw any general conclusion about the time relations of capsule formation or to compare the speed of encapsulation of abscesses due to different organisms.

Of the two cases without a capsule, one in which cerebral symptoms had been present for a week was due to anaerobic streptococci, and the other, in which symptoms had been present for a fortnight, was due to *Strep. pyogenes*. It is clear that no deductions as to delay in capsule formation should be drawn from these two presumably recent abscesses. The same argument applies to the three abscesses in which the absence of a capsule was noted at operation. One of these with a fortnight's history was due to *P. vulgaris* and anaerobic streptococci, one with a three-weeks history to fusiform bacilli and anaerobic streptococci, and one with a four-weeks history to *Staph. aureus*.

There are repeated statements in the literature (Neumann, 1909; Alpers, 1939; Grant, 1941) that anaerobic and Gram-negative bacilli inhibit capsule formation. Histological examination demonstrated well-formed collagenous capsules in two cases in this series from which fusiform bacilli were isolated (in one case together with anaerobic streptococci and in the other with streptococci seen only in films). One of these cases has already been cited by Falconer *et al.* (1943), who found that encapsulation occurred in brain abscesses caused by the intracerebral inoculation of fusiform bacilli or anaerobic

streptococci in rabbits. There is therefore both clinical and experimental evidence that encapsulation does occur in the presence of fusiform bacilli or anaerobic streptococci. Similarly the authors just cited showed that encapsulation occurred in experimental abscesses due to *P. vulgaris*, and well-formed capsules were found in two abscesses in this series in which *P. vulgaris* was present. These observations agree with Atkinson's (1934) statement that *P. vulgaris* is apparently a highly virulent in brain abscesses, but do not support the statement, probably derived from Lund's (1926) record of two fatal cases due to coliform bacilli, that Gram-negative bacilli inhibit capsule formation. Thorotrast, which favours encapsulation (Falconer *et al.*, 1943), had not been introduced into abscesses considered here.

Summary

Specimens of pus from 48 brain abscesses were examined. Details of the cases, of the bacteriological technique, and of the organisms isolated are set out. Of the cases 33 yielded a single organism, 14 more than one species of organism. One specimen was sterile.

Staph. aureus was present in 15 cases, fusiform bacilli and anaerobic streptococci each in 10 cases, *Strep. pneumoniae*, *P. vulgaris* and *Strep. pyogenes* each appeared in several cases. "Streptococci" were found in 21 cases, but several species were represented, the statement that streptococci are the commonest organisms in brain abscess is misleading.

Anaerobic culture is a necessary part of the examination of pus from brain abscesses both for the isolation of obligate anaerobes and for the isolation of some strains of pneumococci.

Data concerning the encapsulation of the abscesses were sufficient to permit any general conclusions about the rate at which the capsule is formed or the effect on that rate of the species of the infecting organism. Two abscesses from which fusiform bacilli were isolated were shown histologically to be well encapsulated, were two abscesses from which *P. vulgaris* was isolated. The cases and some experimental studies (Falconer *et al.*, 1943) are in variance with the statement that anaerobic and Gram-negative bacilli inhibit capsule formation.

I wish to thank Dr. Dorothy S. Russell for allowing me to use her histological findings in the discussion of capsule formation, the neurosurgeons, particularly Brig. Cairns, without whose help this study could not have been undertaken.

ON THE HANDLING OF SMALL BIOPSY MATERIAL

BY

ALAN C. LENDRUM, M.D.

Lecturer on Pathology, the University of Glasgow;
Assistant Pathologist, Western Infirmary, Glasgow

The increasing frequency of diagnostic biopsy, especially of the epithelium of the uterus and the respiratory tract, has prompted this description of the technical procedures used in this laboratory. First, however, it is important to state that biopsy material removed with a blunt scalpel or curette, or subjected to squeezing, tearing, crushing, or deep coagulation during removal will, no matter how good the technique of the pathologist, show nuclear changes that are characteristic of intravital trauma; it should be more widely known that these changes may make the difficulties of histological diagnosis insurmountable.

Many of the methods to be described are of long usage, and are due to predecessors or colleagues; a few are personal innovations, but all have formed an established and satisfactory routine for several years. The importance of scrupulous technique in the handling of such delicate material can scarcely be over-

emphasized, and the description and recommendations are therefore given in a somewhat dogmatic tone.

Fixation

The fixative used exclusively is formal-corrosive. This is prepared by adding 10 parts of commercial formalin (not neutralized) to 90 parts of saturated aqueous solution (5.6%) of mercuric chloride; to this is added enough saturated aqueous magenta acid (acid fuchsin) to give a pale pink colour (depth of 1 in 20,000 KMnO_4). This mixture keeps satisfactorily for months. The addition of the dye has the advantage not only of distinguishing the solution in the laboratory but of imparting to the small fixed fragments a very visible and so helpful red colour. The fixative is supplied in 4-oz. wide-mouthed bottles with bakelite screw caps, about three-quarters full. Metal caps must not be used. The tissues are dropped direct into the fixative, although with endometrial curettings it is of proved value to follow the method employed by Dr. Adam Barr, gynaecologist to this hospital. The curettings are dropped on to an adjacent sterile towel, and the theatre sister, with clean forceps, immediately transfers the fragments of tissue into the fixative. Fixation should be for eight or more hours; in practice this means until the following morning. The tissue is then transferred direct to 95% ethanol (methylated spirit) in a 4-oz. wide-mouthed glass-stoppered specimen jar, where it lies till evening.

Dehydration is completed by transfer to "absolute spirit" (industrial methylated spirit 74 degrees overproof) or absolute ethanol, in which the tissue lies until the morning of the next day (second day after biopsy). **Clearing** is done by benzol (commercial 90%), into which the tissue is now put; two hours is usually enough. Thanks to the fuchsin the cleared tissue is still easily visible—an important point. **Paraffin impregnation** follows, and at 54° C. is adequate in three to six hours (depending on the size and consistency of the tissue). The tissues are thus ready for cutting by the evening of the second day after operation; in practice they are usually cut and stained the following morning.

Notes and Comments

The use of a fixative containing mercuric chloride holds the fragments together by the rapid coagulative effect, and gives a much better fixation of nuclei than fixing for the same period in ordinary formal-saline. The absence of a chrome salt (as in Zenker's solution) removes the need for washing out the fixative, while the presence of formalin in the mixture produces a better fixative for diagnostic purposes than plain aqueous corrosive sublimate (Lendrum, 1941a). It is of course necessary to remove the corrosive by treating the sections with iodine during their hydration before staining.

The fixative thus used is generally quite suitable for filtering and subsequent re-use in fixation of the more gross surgical tissues; the bottles are scrupulously cleaned before refilling with fresh fixative.

In handling small bits of tissue it is of great help to use, as Dr. Janet Niven suggested, dental plugging forceps rather than the usual tissue forceps; they certainly add a noticeable delicacy to the touch.

Denser and tougher tissues (such as biopsies of skin) can be subjected to the same routine if the pieces are small. If, however, a piece is thought to be too large one can cut it with a sharp knife after eight or more hours' fixation, knowing that the face thus cut, thanks to the coagulative power of the corrosive, is not likely to distort. In practice the larger fragment of tissue is left uncut until the next morning; it is then bisected (e.g., through a suspected ulcer), returned to the fixative till midday, then transferred to 95% ethanol, and in the evening to the "absolute spirit" as usual.

If an unsuspected toughness or hardness in a tissue is discovered only when the block is being cut on the microtome, the following procedure is used. The mixture called "mollifex" (B.D.H.; see Baker, 1941) has the power of softening tissue in a paraffin block. In practice if such a troublesome tissue is encountered the paraffin block, still on its wooden chuck (see Carson, 1941), with the tissue already exposed by the attempted cutting, is immersed in mollifex for three or four hours (or till the next day), and it is then found that a satisfactory section can usually be cut. Glycerin has a similar but slower action. If unsuspected calcification is revealed at the stage of cutting, the block and chuck are immersed

in a modified Ebner's decalcifying solution (6% mercuric chloride in 15% sodium chloride, with 1% of hydrochloric acid), and by the following day it is usually possible to obtain a satisfactory section. Slightly longer staining with haematoxylin is necessary because of the acidity of the tissue.

Lymph nodes present a particularly difficult problem, and, since diagnosis of the reticuloses is so dependent on perfect histology, they should be treated by a slower method of dehydration (Lendrum, 1941b).

Summary

Satisfactory diagnosis of biopsy material demands good technique on the part of surgeon or gynaecologist and of the pathologist.

The routine as used at the Western Infirmary Laboratory is described in detail, and recommended as being capable of giving consistently good results.

Medical Memoranda

Congenital Atresia of the Oesophagus

In recording a case of congenital atresia of the oesophagus in the *Journal* (Nov. 12, 1938, p. 983) J. W. D. Bull says: "The following case is recorded not on account of its rarity but because the condition has been so seldom mentioned in the English literature." For the same reason it may be worth while to record another case, in which the fistulous tract opened at the extreme end of the trachea between the bronchi, thus differing from Dr. Bull's case, in which the opening was a little way up on the posterior wall.

CLINICAL HISTORY OF CASE

The mother attended ante-natal clinics and was confined at this hospital. She was a primigravida aged 33. As in Dr. Bull's case, hydramnion had been noted. Apart from premature rupture of the membranes labour was normal. A female child was born on March 17, 1943, at about 35 weeks' gestation. She weighed 4 lb., measured 17½ in., and was apparently healthy. The following night the child vomited thick mucoid material. Cyanosis and rapid shallow respirations were noted. Oxygen, brandy, and glucose were given, but it was found that the child seemed better when left alone. Next day the vomiting continued and fluid was regurgitated through the nose. Cyanosis occurred after each feed and disappeared when the vomiting ceased. Inspection of the palate showed no abnormality, and tracheo-oesophageal fistula was tentatively diagnosed. Feedings were stopped and rectal and subcutaneous glucose-salines substituted. Later the same day frothy white material was ejected from nose and mouth, during which cyanosis persisted. Meconium was passed per rectum. The following day the condition was similar, and the child died early next morning—i.e., after three days.

Post-mortem Examination.—Since the essential points are shown in the photograph, it will suffice to say that no other abnormality was discovered and to describe the procedure. After removal of the thoracic and abdominal viscera in one piece, a metal catheter was passed into the oesophagus from above and was arrested after about 14 in. The oesophagus was opened on to the catheter and found to end blindly. After opening the stomach the catheter was passed up the oesophagus from below. It passed quite readily and emerged from the larynx. Cutting down on to the catheter showed that the lower part of the oesophagus entered the trachea at its bifurcation. There was no evidence of bronchopneumonia, which is apparently the usual cause of death in such cases.

Photograph of specimen

The specimen is now in the Teratological Section of the Museum of the Royal College of Surgeons. In the accompanying photograph the highest pin impales the epiglottis. The metal stylet lies in the trachea and shows the fistula proceeding from the trachea and opening into the stomach. The blind sac of the upper part of the oesophagus is opened and pinned out. The trachea and bronchi are shown opened.

I am indebted to Dr. J. Laurie, medical superintendent, for permission to publish the case, and to Mr. Beggs, clerk of the hospital, who kindly took the photograph.

WALTER CALVERT, D.R.C.O.G.,

Late Obstetrical Officer, Sharoe Green Hospital, Preston;
now Obstetrical Officer and Deputy Medical Superintendent,
dent, Stepping Hill Hospital, Stockport.

Ether Clonus treated by Hexobarbitone Soluble

The following case may be considered of sufficient general interest to be recorded.

An obese woman aged 47 was admitted with an acute appendix. Anaesthesia was induced with gas-oxygen-ether given through a standard Boyle apparatus. Induction was uneventful, but just as the surgeon had opened the peritoneum contractions began abruptly and, so far as could be judged, throughout the whole body simultaneously. The anaesthetic was withdrawn at once, and pure oxygen given under as much pressure as was possible with the apparatus being used. The contractions continued with extreme violence and did not permit of a single complete inspiration. Cyanosis rapidly became extreme; 0.5 g. of hexobarbitone soluble (civapan sodium) was dissolved in 5 c.cm. of distilled water and administered intravenously. No more than 1 c.cm. of the solution had been given when the clonus ceased abruptly. The remainder of the solution was slowly injected and the operation was completed without difficulty. No more anaesthetic was required.

It may be noted that: (1) It is very difficult to enter even a good vein when clonus is present, and almost impossible to be sure of not spilling the solution into the surrounding tissues. (2) Induction required a rather large amount of ether; the appendix was gangrenous, and the theatre unusually hot owing to black-out conditions.

Evesham General Hospital.

H. L. HEATH, M.B., Ch.B.

Unusual Cases of Diphtheria

In view of the recent note by Dr. Manuel Anderson (*Journal*, July 24, p. 104) on an unusual case of external diphtheritic membrane the following cases seem worthy of record.

CASE I

A boy aged 4 years was admitted to this hospital on Dec. 14, 1940, from the Royal Liverpool Children's Hospital, with large patches of diphtheritic membrane on both tonsils. He had been given 10,000 units of antidiphtheria serum before admission, the throat swab being positive. Shortly before developing the faucial diphtheria he had had a second-stage Edmund's operation for hypospadias.

On admission it was observed that the glans penis was very oedematous and that there was a yellowish membrane covering it, blackening in the area of the corona. Cultures taken from this were positive for the Klebs-Loeffler bacillus. A further 40,000 units of A.D.S. was given; the whole penile slough thickened and blackened, and was removed with hydrogen peroxide. The general condition rapidly improved. On Jan. 6, 1941, swabs were taken; the throat proved negative, but the penis positive, as it was again one week later. There were two catgut sutures in the region of the corona; these were removed, and on Jan. 16 a negative swab as obtained.

CASE II

On Jan. 29, 1941, a woman aged 25, with her child aged 5 weeks, was admitted to hospital. The mother had faucial diphtheria with a large patch of membrane on the left tonsillar area. A swab was positive. The course of her case was normal, although in view of her feeding the baby I swabbed the nipples, which were negative for K.L.B.

The child was the interesting case. Before admission there had been a nasal discharge and epistaxis, and the nasal swab was positive for K.L.B. Three weeks previously the child had been circumcised, and there was a filmy membrane on the glans penis and also on the umbilicus, which was still moist. Cultures from both these areas were positive for K.L.B. The throat was negative. 16,000 units of A.D.S. was given. On Jan. 31 there was still some nose-bleeding, but the umbilicus was drying rapidly, forming a blackish scar. The condition of the penis was much the same. On Feb. 3 the black scar had dried and lifted off, leaving a clean healed area. On Feb. 14 small blisters appeared on the penis, but these were negative for K.L.B. and soon cleared up. The mother and child were discharged on March 1, 1941, with swabs from all areas negative.

COMMENT

As in Dr. Anderson's case, undoubtedly the "raw" areas were ready to be "inoculated" with K.L.B. In these cases trauma was not slight, however; but perhaps the cases bear out the suggestion that trauma plays some part in the introduction of the Klebs-Loeffler bacillus.

I should like to thank Dr. Hillman Gray for access to the records.

JOHN W. CROWTHER, M.B., Ch.B.,

Late Medical Superintendent, Dutton Isolation Hospital.

Reviews

EXAMINATION OF THE CHEST

Chest Examination: The Correlation of Physical and X-ray Findings. Diseases of the Lung. By Richard R. Trail, M.D., F.R.C.P. With foreword by Sir Walter Langdon-Brown, M.D., F.R.C.P. (Pp. 10 illustrated. 10s. 6d.) London: J. and A. Churchill, 1943.

Wing Cmdr. Trail has written the little book which many of his colleagues have thought of writing but have hitherto shirked the task. Its main purpose is to correlate the anatomy and pathology of the lungs with the physical findings—clinical and radiological. The book contains two sections. The first consists of a very useful summary of the static and dynamic anatomy of the lungs, including the normal radiological appearance. The second and main section correlates the abnormal physical and radiological findings in common chest diseases with the pathology. This is well done, and the section contains much information not readily accessible to students. Wing Cmdr. Trail is very dogmatic, as is essential when writing for students, but many of the statements concerning the deductions which can be drawn from physical signs are by no means generally accepted. It is a pity that these were included, because many of the less orthodox claims could have been omitted without loss to the general clarity of his explanations. The two sections containing notes on physical signs and on reading films of abnormal chest conditions bear evidence of their origin in lecture notes, as the author explains in the preface. The former gives many useful hints, but the subsection "Crepitations" will not clear the muddle which exists in many students' minds when classifying adventitious sounds. The section on reading x-ray films suffers from brevity and from insufficient diagrams and reproduction of conditions described, but internal evidence in the text suggests that this is the fault of the publishers rather than the author.

A small volume on these subjects was needed badly, and students will learn much from the careful study of the book. Readers must, however, realize that some of the explanations are useful hypotheses rather than proven facts, and not discouraged if they fail to obtain as much information as the author does from the physical examination of the patient.

PHYSIOLOGICAL BASIS OF MEDICINE

The Physiological Basis of Medical Practice. By Charles Herbert Best, M.D., D.Sc., F.R.S., F.R.C.P., and Norman Burke Taylor, M.D., F.R.C.S. Ed. Third edition. (Pp. 1,942; illustrated. 55s.) London: Baillière, Tindall and Cox, 1943.

We welcomed the second edition of this valuable book after its appearance in 1939, since when it has been reprinted three times. Now that a third edition appears we need only repeat our praise, for with one exception the book stands much the same, though there has been revision of detail throughout. The exception is the contribution of Dr. A. M. Wynne on intracellular respiration, which has been entirely rewritten. This is a subject of such growing importance in biochemistry that a brief review of its complexities may be of interest. Intracellular oxidation is primarily concerned with liberation of free energy in the living cell. It is not true, as used to be said, that "all life depends on oxygen," if that statement is read as it stands, for certain organisms and anaerobic bacteria can obtain energy in the complete absence of oxygen by rearranging the atoms in, for example, glucose. In all fermentations there is a cleavage of the molecule, the oxidation of one half being achieved by the reduction of the other half. Even in animal tissues there is an anaerobic mechanism for the liberation of energy. In muscle this comes into play when there is an acute need for energy which the oxygen supply is inadequate to meet. On the other hand, when the oxygen supply is abundant it suppresses the fermentative method. The utilization of intracellular oxygen was studied by Warburg, who revived interest in the muscle pigments detected by McMunn as long ago as 1886, which were subsequently found to be iron-porphyrin compounds. But Warburg's conception of this as a "respiration enzyme" was inadequate to explain the observed facts. Keilin renamed the pigments cytochromes, of which there are three—a, b, and c. He showed that in whatever way oxidation was effected it involved the loss of one or more electrons, which were regained on reduction. Intracellular

REVIEWS

idation is achieved by handing on an electron from the iron in the cytochrome to the next in the series, thus becoming oxidized itself and reducing its neighbour by means of the gift thus received. Such in barest outline is the remarkable story. The book is a valuable work of reference, but, as we said before, the particular need now is for books on the principles of physiology and medicine side by side with such admirable encyclopaedias.

PROBLEMS OF POST-WAR EUROPE

When Hostilities Cease. (Pp. 124. 4s. 6d.) London: Victor Gollancz, 1943.

This booklet contains papers on post-war relief and reconstruction that were written for the Fabian Society. Julian Huxley writes on relief and reconstruction, H. J. Laski on the machinery of international relief, W. Arnold-Foster on international controls, John Marrack on food for starving Europe, John A. Leck Bourne on post-war medical relief in Europe, and Kenneth Hammond on relief measures for agriculture, and Kenneth G. Brooks on the re-establishment of displaced peoples. Leonard Woolf contributes the introduction, and there is a foreword by Philip Noel-Baker. The introduction states, "The citizen who has read this book cannot evade responsibility for the plea of ignorance, for he knows the facts, the problem, and the policy of action which the Government of his country should adopt. It remains, therefore, for him to see that his Government adopts it." Such an *ex cathedra* utterance is unfortunate; it is certainly an over-simplification. The reader will find stimulating accounts of numerous aspects of post-war relief, but some of the views expressed are unlikely to secure universal approbation. There are, indeed, divergencies of opinion among the authors of this book; it would be surprising if it were not so. There is, however, general agreement that post-war relief should be much more than a mere salvage operation or an act of charity. Relief must be a prelude to reconstruction; it should be the first step in practical international economic co-operation, an integral part of the future international organization. It is very desirable, then, that relief and reconstruction should be planned and administered with due regard to the structure and attributes of the future "League of Nations." Some international controls will be essential as soon as hostilities cease, and in many fields such controls must be permanent and more effective than any that the League of Nations was ever able to secure. The political failure of some of its technical organizations—such as the International Labour Office and the Economic and Health Sections. In the fields of public health and medical research and readjustments, might make a very valuable contribution to post-war relief and reconstruction. In any case the medical profession will have a vitally important part to play in the rehabilitation of this war-stricken world, and for that reason, if for no other, the subject-matter of *When Hostilities Cease* is of immediate concern to it.

In describing the magnitude and scope of the post-war catastrophic conditions that will call for relief much is inevitably based on conjecture and on analogy with conditions after the last war. The book is not altogether free from errors. Thus in the chapter which deals with food for starving Europe it is stated that "the number of cattle in Germany fell from 20,994 in 1913 to 17,227 in 1918." These are impossibly low figures. Elsewhere in the book the probable deficiency in numbers of cattle in Europe, excluding Russian losses, is given as 10,000,000 head.

Notes on Books

The Governors of the Royal Cancer Hospital, London, have authorized the republication of selected papers from that hospital and the associated Chester Beatty Research Institute. The first volume appeared at the end of last year and was briefly noticed in this column on April 10. Volume 2 has now been issued. Like its predecessor, it is a substantial book, and it comprises 34 papers published during 1939 and 1940. All the articles are well reproduced by the Replika process, and they cover a wide range of subjects related to cancer, its genesis and treatment. By far the longest

contribution is an important paper by Prof. J. W. Cook and Prof. E. L. Kennaway entitled "Chemical Compounds as Carcinogen Agents: second supplementary report: literature of 1938 and 1939 reprinted from the *American Journal of Cancer*; this occupies 309 pages. Copies of Volume 2 are available at a cost of 16s. p. 90 and may be had on application to the Secretary, Royal Cancer Hospital (Free), Fulham Road, London, S.W.3.

A fifth edition of *A Guide to Anatomy*, by E. D. EWART, has now been published by H. K. Lewis at 17s. 6d.: Written originally in 1920, this book has proved useful to a long succession of students preparing for the examinations held by the Chartered Society of Massage and Medical Gymnastics, and it has grown much with the passage of years. Dame Barrie Lambert, who helped the author with the first draft, writes a foreword to the new edition.

Eight Hundred Years of Service: The Story of Britain's Voluntary Hospitals is the title of a neat and attractive pamphlet issued by the British Hospitals Association (12, Grosvenor Crescent, S.W.1). The spirit of hospital service, and a good many of its details to could not have been more pitifully set out in fewer than a score of pages. The title, perhaps, is open to a little question. It is true that St. Bartholomew's has had more than eight hundred years of history, but, apart from that great foundation and St. Thomas's, the story of hospitals so far as London is concerned, and most of the English counties as well, is a very thin one until the beginning of the eighteenth century. The pamphlet does not attempt any definition of what "voluntaryism" means, but it describes in a terse fashion the triumph of planning which a modern hospital represents, and the humanity of its administration, with a brief account of the great medical discoveries and achievements that have taken place within its walls. The object is to show the general public how voluntary hospitals can take a major part in the coming co-ordination of hospital services.

Preparations and Appliances

AN ENDOTRACHEAL HARNESS

Dr. M. W. P. HUDSON writes from Queen Mary's Hospital, Roehampton:

The device shown in the illustrations is designed to prevent the drag of the accordion tubing on the nose and to avoid separation of this from the endotracheal tube during anaesthesia. It consists essentially of a rubber band three inches wide and ten inches long with a tail-piece sixteen inches long. The centre portion has two parallel slots through which the junction tubing is threaded: at one end there is a stud; at the other end the tail-piece has a series of holes.

The main portion is laid on the forehead and the junction tubing is threaded through the slots: the tail-piece is then passed immediately above the ear, behind the head below the occiput, and immediately above the ear on the other side. Tension is adjusted as required and the tail-piece is fixed by pressing the appropriate hole on to the stud.

It will be noted from the figure that no movement can occur between the nose and the point of fixation however much the position of the head is altered during an operation. I wish to thank the Director-General of Medical Services, Ministry of Pensions, for permission to publish this note. Mr. T. P. Kilner for his encouragement, and Mr. J. E. L. Mayes for the photographs. The harness can be obtained from Medical and Industrial Equipment, Ltd., 12, New Cavendish Street, London, W.1.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 20, 1943

MEDICINE AND SOCIETY

If civilization means the art of living together in towns we cannot yet be sure that our civilization will survive. We have removed the major pestilences of town living and we are on the way to remove some of its discomforts, but new problems arise as the old problems are removed and we are hard pressed to keep pace with our self-created troubles. The success of our efforts will be judged on the rate of our progress and by our wisdom in the choice of means of achieving it. Some of this disquiet is evident in medicine to-day; it finds expression in a rising interest in social medicine, and in a demand that the medical profession, by research, teaching, and practice, should play its appointed part as no other profession can. This interest in social medicine is tinged with some misgivings about its objects, and there are fears that if it is pressed upon the student the intellectual discipline of the old clinical training will be replaced by a loose sentimentalism of the new. Prof. John Ryle's description of the meaning and scope of social medicine, printed in our opening pages this week, should do much to remove these doubts. There will be no great dissension from his view that the last generation of medical students have directed too much time to the details of technical diagnosis and specialized treatment; that they had been engaged too much on the study of how men die and too little on the study of how men live. The fault does not lie entirely at the door of the clinical teachers. They may have followed too much the intellectually satisfying pursuits of technical diagnosis, but on the other hand their field of study has been narrowed by unhappy accidents of legislation and administration which have relieved them of those responsibilities which an earlier generation of teachers shouldered. This is one of the reasons for the decline in their interest in any of the common diseases of civilization.

The Royal College of Physicians of London has recently published the interim report of its Committee on Social and Preventive Medicine, and this indicates the lines upon which the teaching of social medicine might be developed.¹ The committee has foreseen the danger that social medicine might become merely another specialism added to the student's curriculum or tacked on to the existing public health course. Its recommendations include practical suggestions for a scheme of training which would help the student throughout his clinical years. The first aim of the training in social medicine would be to indicate to the student the industrial and social factors which contribute to the causation of disease and to train him in the practice of social investigation. The next aim would be to demonstrate the structure and working of the various social organizations provided by local authorities and

voluntary agencies. With this knowledge the doctor would be able to make better use of these instruments for the benefit of his patients. But we must expect still greater results. If the medical profession had a deeper interest in the efficiency of the instruments of medical aid it might bring the steady pressure of its opinion to bear on the reform. We are faced by many schemes of social reform. Not a few of these concern the doctor and the agencies he uses. He should be able to assess the efficiency of an institution as readily as he assesses the effects of other forms of treatment.

It will be difficult straightway to set up in all medical schools departments of social medicine, and it is important that this should not be done until suitable head departments are available. But this does not mean that nothing should be done. In most medical schools there is at least one teacher with an "interest in humanity who could arrange and inspire if the responsibility were placed upon him. If he did no more than arrange with his colleagues that time and place should be found for the instruction of students he would have done much. Beyond that there is the practical task of bringing the almoner's department into its proper status, of organizing a student's health service, and of improving the hospital social machinery. It may appear strange that hospitals should need "humanizing" in some of the ways that are recommended in the report of the Committee of the Royal College of Physicians, but it is no more strange than the first recommendation that the College "should take an active interest in the organization of the teaching of social and preventive medicine," for there was a time when it was expected to advise on all matters concerning the health of the people and to suggest means for its improvement. We shall await with interest the fulfilment of the promise that in its next report the Committee on Social and Preventive Medicine will discuss the arrangements of social medicine outside the hospital. Here it will be in touch with problems more difficult than the teaching of students or the arrangement of almoners' departments.

TREATMENT OF GAS GANGRENE

The concerted study of gas gangrene planned shortly after the war began is now bearing fruit. The Middle East has for long been the only theatre of operations in which an abundance of clinical material was available, and the excellent use made of it is evident from the papers of J. D. MacLennan,¹ whose study is classical in its scope and thoroughness. He was enabled not merely to obtain information about all cases of gas gangrene among the casualties in a whole series of campaigns, but personally to investigate a large proportion of them. Full bacteriological data, such as are only forthcoming when an expert examines the original material, are thus available for correlation with clinical findings. MacLennan's definition of various types of anaerobic wound infection distinguishes several other conditions from true gas gangrene, and among cases of the latter there were enough due to the more uncommon *Clostridia* to define, in some cases

¹ See *British Medical Journal*, Oct. 30, 1943, p. 553.¹ *Lancet*, 1943, 2, 63, 94, 123.

the first time, the clinical picture which they produce. Two points which emerge clearly are the graver prognosis in mixed infections, and the invariable fatality of infection by *Cl. histolyticum*. Sulphonamide treatment was disappointing—a fact for which the frequent occurrence of *M. oedematiens* in Libya may be partly responsible, since his organism is relatively insusceptible; combined sulphonamide and antitoxin treatment was clearly more effective.

The organization which worked so well in Libya has naturally had no parallel in the more scattered medical services in this country, nor has any considerable number of cases ever been available at one place and time. The best that could be done was to collect information about diagnosed and treated cases after the event, and Army Form I 1241 was issued to the Services and to the E.M.S. for this purpose three years ago. Returns on this form have now been collected and analysed by Miss M. G. Macfarlane, who describes her findings on page 636. Excluding 88 Dunkirk casualties, about most of which the information was inadequate, and 85 North African cases included in MacLennan's series, her material consists of 165 reports from various sources, including casualties in all three Services treated in this country, recent casualties in the B.N.A.F., and civilian air-raid cases. Unfortunately no bacteriological data are included; the nature of each case is defined only in terms of the site of the lesion and the degree of toxæmia judged to exist on clinical grounds. Nor are any conclusions drawn with regard to the value of sulphonamide treatment; almost all patients received it, and presumably an analysis of response in relation to dosage or choice of drug is not thought feasible. Gas gangrene calls for sulphonamide dosage on the highest possible scale, and if material becomes available for judging its effect a comparison between cases so treated and those given the ordinary doses more appropriate to a less acute emergency might well be made. What this analysis does afford is evidence of the value of antitoxin treatment. From this point of view the data are examined in every possible way, and it emerges clearly not only that the general fatality rate is lower in antitoxin-treated cases but that this applies equally to cases also treated by surgical measures, including amputation, and that early administration is more effective. The main lesson to be learned from this series is that a dose of not less than 50,000 units of antitoxin should be given with the least possible delay; a few hours may be vital in a disease of which the progress is so rapid. Amputation was performed in 64 of the 139 cases; this, and an over-all mortality of 41%, make up a somewhat discouraging picture.

The frequency of amputation suggests that there may have been a tendency to report only more severe cases. That those reported represent only a small fraction of those that have occurred is almost certain: no one is going to believe that in the whole period of the air war on Britain the number of civilian casualties suffering from gas gangrene in hospitals under the control of the E.M.S. has been only 38. Perhaps the publication of these findings may lead to more consistent notification and reporting, but it is doubtful whether form-filling research can ever

in any way take the place of personally directed investigation. We would nevertheless emphasize, not for the first time in these columns, the obligation which lies on every surgeon to give others the benefit of his experience.

THE UBIQUITOUS THREADWORM

Seven years ago the chief of the Division of Zoology of the National Institute of Health of the U.S. Public Health Service, the late Dr. Maurice C. Hall, began an extensive research into the various problems of the threadworm. Since then 27 articles by various members of the team of workers employed have appeared in different periodicals, and earlier this year Dr. Eloise B. Cram¹ summarized the work done and came to certain conclusions, some of which are of special interest to the general practitioner. First, it is not sufficiently realized how infectious threadworm infestation is. A single worm may turn out an average of 11,000 eggs; this gives some idea of the extent to which an infected person may be a source of reinfection to himself and of infection to others. Moreover, household studies have shown that the eggs are distributed in the dust of the rooms. Positive findings for eggs, at all levels of the walls, amounted to 91.7% of the samples, and it was concluded that about half of the eggs found were viable or had recently been so. Chemical methods of destroying the eggs were unsuccessful, and it is clear that preventive methods alone cannot control threadworm infection. It is also clear from these American studies that *familial infection is only too common*. If one person in a family is infected, most or all of the children are likely to be infected, and probably also one or both parents. This is true of all classes, and it is clear that treatment of a patient must usually include treatment of most other members of the household. The second big problem concerns diagnosis. Recent studies have shown that nail-biting, thumb-sucking, nose-picking, grating of the teeth, and nocturnal enuresis are no more common in the infected than in the non-infected child. Positive symptoms are restlessness and insomnia, vague gastro-intestinal disturbances, and local irritation. But the clinical picture is blurred, and the fact that out of 4,000 persons examined by the special "N.I.H." swab method 41.5% of whites and 12.9% of negroes were found to be harbouring threadworms shows how pertinacious worms are, since sampling was considered as representing a fair cross-section of the population. The swab method of diagnosis should be more widely used:

"The swab consists of a glass rod with its rounded tip covered with a 25-mm. square of plain, transparent, unwaterproof cellophane, the rod being inserted in a perforated cork fitted in a small test-tube. The cellophane tip is stroked firmly over the perianal surface. In the laboratory the cellophane is detached from the rod, mounted in water or tenth-normal sodium hydroxide solution, and examined under the microscope for the presence of pinworm eggs."

The best time for taking the swab is immediately after the patient gets up in the morning—before a bath or evacuation of the bowels. The efficacy of treatment has been checked in the American series by requiring 7 consecutive negative daily N.I.H. swabs beginning from the tenth to the forty-second day after the end of treatment. Most popular remedies come badly out of this strict test. The only way to control this widespread infestation at present is to tackle all infected persons in a household with an effective anthelmintic. This must be relatively un toxic, cheap, and easily administered. The most nearly satisfactory drug tested was gentian violet; although treatment with this was described in this country some time ago,

¹ *Am. J. Dis. Child.*, 1943, 68, 46.

it has apparently not attracted sufficient attention, as judged by inquiries received in the "Any Questions?" section of this *Journal*.

"The dosage of the drug for adults was two 32-mg. (1/2 gr.) tablets three times a day before meals and for children 10 mg. (1/6 gr.) a day for each year of apparent (not chronological) age, the total daily amount of the drug for children being divided into three doses. The routine of treatment was varied in different series of tests with a view to determining the most suitable regimen. Part of the patients were given the drug for ten consecutive days, and part were treated for eight days, allowed to rest for seven days, and then re-treated for an additional period of eight days. Both enteric-coated and water-soluble-coated tablets were employed."

A fair proportion of patients experienced some degree of gastro-intestinal upset while gentian violet was being used, but such symptoms subsided quickly when the dose was reduced or if the drug was omitted for a day or two. The method should not be used if there is a concomitant infection with roundworms, with moderate to severe cardiac, hepatic, or renal disease, and any disease of the gastro-intestinal tract. The American summary also includes as a contraindication "alcohol in the digestive system."

PENICILLIN IN TUNISIA

The meeting of the Section of Experimental Medicine and Therapeutics of the Royal Society of Medicine on Nov. 9, the proceedings of which are reported elsewhere in this issue, attracted a large attendance. By common consent the film by which Prof. H. W. Florey illustrated his recent experiences in penicillin treatment was accorded the chief welcome among several notable contributions to the study of this subject. He spent the summer months in Tunisia, evolving, with the help of Army surgeons, methods of treating battle wounds to prevent sepsis. The film first depicts the conditions under which wounded have to be nursed, prominent among which are shade temperatures never below 90° F., clouds of dust sweeping over the tents from every passing vehicle, and swarms of flies settling on every exposed wound. The cases treated had been evacuated from Sicily, and treatment was usually begun several days after wounding, when infection was already established. The method adopted for wounds of soft parts, however extensive, was excision of the skin edges and of damaged tissue bordering the wound, and complete suture, leaving the wound cavity several narrow tubes, secured in stab incisions bordering the wound, through which penicillin solution was injected at intervals subsequently. In a very large proportion of cases primary healing was secured, and some of the wounds were obviously of a nature and extent which must have led to prolonged suppuration and very slow healing by granulation had "orthodox" methods been used. Suture was possible only under considerable tension in some of the cases. Functional results appeared to be excellent, even in cases classified only as "subtotal" union of soft parts. Compound fractures needed more drastic treatment: a penicillin-sulphanilamide powder was introduced into the wound at the C.C.S., and débridement and complete closure at the Base were followed by about 5 days of systemic penicillin treatment, a total of usually 500,000 units being given by 3-hourly intramuscular injections or by intravenous drip. This method of controlling sepsis in an even more difficult type of case appears also to have achieved a remarkable degree of success, and months of invalidity can evidently be avoided by this method. It is now abundantly proved that wherever penicillin can be continuously maintained sepsis due to Gram-positive bacteria cannot exist: repeated infiltration through

tubes can secure this condition in wounds of soft tissue after closure, but nothing short of systemic treatment serve the purpose when bone is involved. No one sees this remarkable testimony to the possibilities of penicillin treatment in dealing with battle wounds will give the large share of available supplies which the Army doubtless receive until the end of the war.

Gas gangrene due to either of the three main toxic species of *Clostridia* should be susceptible to penicillin treatment, judging by the *in vitro* susceptibility of the organisms and by the results at least of prophylactic use in mice. Information about therapeutic effects in gangrene has been awaited with interest, and it was somewhat disconcerting that the first clinical evidence on subject should consist of the 4 cases described by Elliott C. Cutler of the U.S.A.M.C. which developed gangrene actually during treatment with penicillin compound fractures. It would be interesting to know what the infecting organisms were and whether they exhibited corresponding resistance *in vitro* and in the experimental animal. Two of the cases were in members of Flying Tress crews wounded in action over Germany. The seems a strange place to get gas gangrene, and contaminated clothing is presumably the only possible source of infection. It was said of the German Navy in the war that before they put to sea every man was ordered to have a hot bath and put on clean underclothes and uniform in order to avoid sepsis if casualties occurred. Whether such measures are either feasible or worth while for the crews has no doubt been considered.

MINISTERIAL CHANGES

Of the new Cabinet appointments announced last week two of them are of the greatest interest to the medical profession—that of Mr. H. U. Willink, K.C., as Minister of Health and that of Lord Woolton as Minister of Reconstruction. Lord Woolton has been more than a distributor of the nation's food during wartime. Guided by first class scientific advice, he has in fact become "Minister of Dietetics," and has done much to instruct the people of this country that the greater part of good health is good food. If he is as successful in his new Ministry in providing "food, houses, and work" for peacetime Britain then the ground will be clear for Mr. Willink—the new Minister of Health—to reconstruct the health services of England and Wales. Mr. Willink is under 50 and comes to the task with his recent record of successful achievement as Special Commissioner for the London Region. As son-in-law of Dr. H. Morley Fletcher he will have personal acquaintance with the aspirations of the medical profession. As a former senior Scholar of Trinity College, Cambridge, he will, we can be assured, have real understanding of the ideals of medicine as a learned profession and of the needs and aims of medical education and research, to which the Cambridge departments of physiology and of medicine have made such weighty contributions. He comes into office at a moment when there is confusion of counsel in the profession at large, and a moment when medical distrust of the Ministry of Health is widespread. He will find a medical profession intensely suspicious of doctrinaire plans, but anxious for reform, fully aware of present shortcomings, and eager to respond to a broadminded handling of the problems of health and disease that come within the scope of a central government department. The medical profession has listened patiently to Mr. Ernest Brown, and if he has at times caught the ear of the profession he has never quite touched its heart or its mind. Mr. Brown seemed always to be speaking with two voices—the voice of reason on one day

he voice of the politician on the next. He had a difficult term of office. But he deserves our gratitude for the campaign on diphtheria immunization, for trying to clean up the milk situation, for introducing measures to detect tuberculosis more quickly. Perhaps more than any other man Mr. Brown knows what difficulties lie before his successor—and may Mr. Willink remain in office at least long enough to profit by the mistakes which he, like all Ministers of Health, will probably make.

CONTROL OF DISEASE IN THE TROPICS

The report of the fourteenth meeting of the Ross Institute Industrial Advisory Committee, held in May, gives a very adequate summary of many widespread recent activities in relation to the control of disease in the Tropics. Referring to the work of the Ross Institute, the chairman, Mr. G. H. Masefield, discussed recent successful work in India, Ceylon, and Africa, particularly in the tea and rubber areas in those territories. Sir Malcolm Watson, speaking in more detail of what had been done, paid tribute to Sir Ronald Ross, whose insight had correctly pointed out the way in which malaria could best be combated. Events had shown that what he had said was right in every respect, and had stimulated research in many tropical diseases, such as yellow fever, relapsing fever, and plague, all of which it is now known are conveyed by different insect hosts. The importance of the part played by the London School of Hygiene and Tropical Medicine, in teaching, in conducting laboratory work, and in field researches, was emphasized by Dr. V. B. Wigglesworth, F.R.S. Without a broad scientific foundation applied work soon became sterile and ceased to grow. On the other hand, were it not connected with practical field problems the scientific work of the school would soon become academic. Thus close liaison between the work of the Ross Institute and that of the Entomological Department of the School was most desirable. During the war almost all the workers in the department had been fully occupied with problems of immediate practical importance to the Services. Prof. P. A. Buxton, F.R.S., and Dr. J. R. Busvine had devised new and more effective methods of dealing with the destruction of lice, the carriers of typhus and other diseases—methods which are being extensively employed at the present time in the Middle East. The question of larvicides and the effective blending of waste oils for the destruction of mosquitoes and work on substitutes for Paris green and for pyrethrum, of which there is at present a world shortage, had also been taken up with useful results. Prof. R. T. Leiper, F.R.S., stressed the need for a scientific basis in dealing with the problems of curative and preventive medicine, and referred to the importance of parasitological studies not only in medicine but in agriculture in the maintaining of healthy crops. Col. Mackie, I.M.S., spoke on yellow fever in Africa and the regulations for controlling the spread of this disease. He explained the term "mouse protection test" and its great usefulness by enabling dangerously infected areas to be accurately determined and quarantine regulations made in accordance. He referred to the necessity for controlling mosquitoes, especially a species of *Aedes* and other mosquitoes known to carry the disease in the vicinity of aerodromes, and for destroying insects in aircraft alighting in endemic areas, now carried out with a recognized insecticide and an efficient spraying apparatus.

Sir Eric Macfadyen said that the Industrial Advisory Committee was the direct link between the Institute and industry in the Tropics, and that the linking up of the London School of Hygiene and Tropical Medicine, with its

high repute and its distinguished achievement in scientific research, and the Ross Institute, with its world-wide record of useful service in combating malaria and other tropical diseases, ought surely to be fruitful. The Industrial Advisory Committee was formed in October, 1928, by the late Sir Charles McLeod with the idea of enlisting the help of those largely associated with the control of industry to allow of a quicker appreciation of the possibilities of radical health improvement in the Tropics by the adoption of new ideas in the control of disease.

THE CLINICAL SOCIETY OF LONDON

In his recent presidential address on this subject before the Clinical Section of the Royal Society of Medicine Dr. J. D. Rolleston said that the formation in 1868 of the Clinical Society of London, the parent of the Clinical Section of the R.S.M., was mainly due to Dr. Headlam Greenhow and Dr. (afterwards Sir) John Burdon Sanderson, who were both assistant physicians of the Middlesex Hospital, the latter being subsequently appointed Waynflete Professor of Physiology and later Regius Professor of Medicine at Oxford. According to Dr. Rolleston the most interesting historical event connected with the Clinical Society was the first medical description in this country of x rays, which was made before it nearly fifty years ago. Early in 1896 the society invited Prof. Silvanus Thompson to tell its members about the new discovery. A special meeting was held on March 30, 1896, and was attended by nearly 400 members. Subsequently numerous cases illustrating the diagnostic and therapeutic value of x rays were reported at the meetings of the Society and recorded in its *Transactions*. A remarkable custom in the practice of the Society was the frequent establishment of special committees to describe various subjects or individual cases. The most important of these committees were those on myxoedema, the periods of incubation and contagiousness of certain infectious diseases, and the antitoxin of diphtheria which had just been introduced into this country. The course of the Society was successful from the first. At the time of its amalgamation with sixteen other societies in 1907 it numbered 572 ordinary members and 17 honorary members. The first meeting was held on Jan. 10, 1868, under the presidency of Sir Thomas Watson, who was regarded at the time as the greatest English physician of the century and author of a textbook on medicine which was without a rival for over 30 years. The subjects and cases discussed covered the whole field of medicine in the widest sense of the word. It was a remarkable fact that the subject of acute infectious diseases received much more attention from the Society than it subsequently did from the Section, as is seen from the fact that during the forty years of the Society's existence its *Transactions* contained 50 records of acute infectious disease, as compared with only 15 in the *Transactions* of the Section between 1907 and 1942.

The President and Council of the Royal Society have awarded the Copley Medal to Sir Joseph Barcroft, F.R.S., for his distinguished work on respiration and the respiratory function of the blood; and the Davy Medal to Prof. I. M. Heilbron, F.R.S., for his many notable contributions to organic chemistry, especially to the chemistry of natural products of physiological importance.

The Canadian Medical Association has decided to hold a regular annual meeting next year in Toronto during the week beginning on May 22.

EMPLOYMENT OF THE TUBERCULOUS IN INDUSTRY IN THE U.S.S.R.

[FROM A SPECIAL CORRESPONDENT]

Recent numbers of the journal *Problemy Tuberkuloza*, Moscow, provide interesting information on Russian experience of collective arrangements for employing the tuberculous, or those in whom the disease is quiescent, in industry.

Provision of modified working conditions in ordinary industry seems to have been sporadic until about 1936-7, when more systematic arrangements were made through instructions from the People's Commissariat for Health of the Central Council of Trades Unions (which is responsible for much of the factory welfare services). N. E. Vredenskaya of the Central Tuberculosis Institute gives a critical survey of such arrangements in 25 large factories (including the now famous Barricades Factory of Stalingrad) with an aggregate population of 250,000 and 1,500 tuberculous employees (1938, No. 6). (Over half of the latter had a positive sputum, a proportion probably higher than in comparable industrial populations in this country, even in wartime.) There was considerable variation in the arrangements from one factory to another, but the following were some of the desirable features: preliminary survey of the tuberculous persons employed and of their working conditions; accurate clinical and social records of those requiring modified work; education of and explanation to the mass of the workers; special factory committees with executive powers, representing the management, the tuberculosis dispensary, medical officers, the shop stewards, and the social insurance fund, to plan and control suitable work arrangements; and close co-operation between tuberculosis dispensary and the administration, health centre, and T.U. organizations of the factory.

The arrangements might provide that the tuberculous person continued in the same occupation, but the pace or strain of the work was reduced—e.g., fewer benches, part-time work, no night work, more frequent rest pauses, special rest rooms, extra food from the canteen, etc.—or the occupation might be altered with or without similar amelioration; in the case of part-time workers, any loss in earnings was made up from the Social Insurance Fund. Stress was laid on keeping the skilled worker in a skilled job and, if possible, in his own industry; indeed, it was laid down that in selecting workers who were to be retained when personnel was reduced preference should be given to the tuberculous. Retraining for new jobs took place sometimes at sanatoria, but generally in a special centre within the factory by instructors provided by the management. Trainees received allowances and, where necessary, were accommodated at "night sanatoria" (well-known Soviet institutions). The author concludes that these enterprises show great promise, but are only in an early stage of development, a number of difficulties remaining to be hammered out.

The "Prophylactic Workshop"

One of the methods most favoured in the Soviet Union whereby tuberculous workers can be employed, and one capable of catering for relatively large numbers, including selected infective cases, is the special shop or section within a large factory. An example, which was started in 1938 in the Hammer and Sickle works in Kharkov, is described in some detail by Y. M. Gaft and A. A. Kalinin of the Ukrainian Institute for Study of Tuberculosis (1940, Nos. 2 and 3). First a survey was made of the clinical state, working and living conditions, productive efficiency and earnings, records of temporary absence from work, etc., of all the known tuberculous persons in the factory. A special committee, composed as already mentioned, then interviewed each individual. The work of about one-third of them required adjustment owing to its unsuitable nature (e.g., hot foundry work), hours, or shifts. Some of these people were transferred to more suitable jobs in other parts of the works, if necessary after training, and individual arrangements were made also for highly specialized workers drawing high wages.

In all, 56 persons were transferred collectively to the "prophylactic workshop," including those with effective A.P., fibro-caseous disease, and other types; nearly half of them had

positive sputum. The workshop served as an independent production unit, making locks, spanners, hinges, etc., and its occupations included those of fitter, turner, and so forth. The workers were kept under supervision by the works medical officer in consultation with the local tuberculosis officer. There were no night shifts, and the working day was reduced at rest pauses lengthened as necessary. Extra food was supplied and infective persons ate at a special canteen. In certain cases the worker slept at the night sanatorium; in others a period away at an ordinary sanatorium might be prescribed. Of the 56 cases studied over 2½ years, 13 improved sufficiently to be transferred to normal sections of the works, 24 were still retained in the "prophylactic shop" at the time of reporting, 13 had deteriorated and been invalidated, and 6 had left for personal reasons. A considerable number of those who originally had a positive sputum ceased to expectorate bacilli.

The majority of workers in the special shop showed all subjective improvement; production was satisfactory, and some of them even exceeded their quota. There was less temporary absence than before they were transferred to the special shop. The authors conclude that the "prophylactic shop" has a definite place in the management of tuberculosis in industry. With correct choice of cases and with adequate individual medical care the favourable conditions are beneficial to the course of the disease and help to preserve working capacity though deterioration in unfavourable types cannot be averted.

Special workshops for the tuberculous may also be independent of existing factories, and P. B. Torkanov describes one of these (1940, Nos. 2 and 3) which employ 200 workers making furniture, nails, cardboard, and knitted goods. This undertaking was self-supporting, though the author recommends subsidies from the insurance funds for establishments of this kind. In such shops, owing to the wide selection of patients necessary if they are to cater for large numbers, an absence rate of as much as 30% must be expected; the absences are mainly of persons in whom exacerbation has occurred and those passing a period in a sanatorium.

Retraining the Tuberculous

The retraining of tuberculous persons for new industrial occupations is of major importance in schemes of rehabilitation, and, as already mentioned, this has been considerably developed recently at centres within the large factories. In a further paper (1940, No. 10) Vredenskaya gives some of the advantages of this system—namely, affected persons are retained in their own industry, equipment and instructors can be obtained, and it is comparatively easy to place the worker in a job when trained, and to do so in consultation with the tuberculosis officer who has supervised his medical and social requirements during retraining. Workers are also retrained in special workshops connected with tuberculosis dispensaries with residential sanatoria ("prophylactic work centres"), as this system is described by P. P. Pekar and D. K. Kuryachina (1940, No. 11) and by Y. E. Berensón (1941, No. 2).

The findings of these authors may be summarized as follows: the aim of retraining should be to maintain if not to increase the earning power of the affected worker; tuberculous persons should be retrained who are engaged in work at high temperatures or in dusty occupations, in work involving heavy physical exertion, work in the food industry or in contact with children or who are exposed to toxic hazards or to rapidly changing weather conditions; manual occupations suitable for trainees include those of turner, fitter, electrician, knitting and sewing machinist, etc.; persons with an unfavourable prognosis should be excluded from retraining schemes, the most suitable candidates being those with satisfactory lung collapse or with limited productive lesions; courses of retraining usually have to last 6, 8, or even 12 months.

The enormous transferences of heavy industry since the war have necessitated many adjustments in the Soviet rehabilitation programmes. To make up for inability to use many residential sanatoria, the number of night sanatoria has been increased, and, to supplement these, there is an extensive network of "day sanatoria," most of which are near large factories and providing of assistance in the rehabilitation problem. The employees who are thought by the tuberculosis dispensary to require special care can eat and rest at the sanatorium during

air midday break, while part-time workers can spend their i-time there (Soviet War News, 1943, No. 534).

United Nations' Experience

It is interesting to note that rehabilitation schemes for the tuberculous are developing according to different patterns in different countries. In the U.S.A. there is the "Altro" sheltered workshop scheme in New York City. In England interest has centred round the "village settlement" or colony, either for permanent residence, as at Papworth, or for prolonged or semi-permanent settlement, as at Preston Hall. While in the U.S.S.R. there is wide recognition of the value of the village settlement, Soviet authorities appear to be concentrating upon large-scale rehabilitation of the tuberculous in or around normal sites of industry, mainly by special arrangements within existing factories, though also by separate workshop units. There is no doubt that by these means they hope to provide, within a reasonable time, suitable and safe re-employment for all those needing it, whether they are convalescent and non-infective or chronic, still active (and often infective) cases (i.e., the "good chronics"). In England the war has increased the problem of the tuberculous in industry, for many persons previously idle have re-entered factories and offices and are doing unsuitable full-time work, often subjecting their and young workers to the risks of infection. The war has also increased general interest in the problem and has brought about a realization of public responsibility, as evidenced by the reactions to the recent reports of the Medical Research Council and Tomlinson Committees. The Ministry of Health's new schemes for mass radiography and for financial help will bring the need for systematic tuberculosis rehabilitation schemes to the front. Fortunately, the pooled experience of the United Nations will be available to facilitate a rapid advance in this branch of social medicine.

ASSOCIATION OF PHYSICAL MEDICINE

Nearly twenty years ago, in opening the winter session at the Leeds School of Medicine, Lord Horder (Sir Thomas Horder, as he then was) spoke on physical medicine, and urged the formation of an association to encourage the study of the action of physical agents and their application in the promotion of health. The British Association of Physical Medicine has at long last been formed, with Lord Horder as its first president and Dr. P. Bauwens as its honorary medical secretary.

Inaugural Address

In delivering the inaugural address Lord HORDER said that the birth of the association had come at an appropriate time when the problems of reconditioning and refitting the people of this country, physically, mentally, and spiritually, after their injury in all these aspects by a life-and-death struggle against a sporadic outburst of barbarism had to be faced. There could be no rigid boundaries of physical medicine, but it might be said, on Brig. F. D. Howitt's definition, to have three functions: the achievement and maintenance of physical fitness; diagnosis and treatment, by physical means, of disease and disability of the locomotor system; and the physical selection, training, and reinstatement of personnel in industry and the armed Forces.

"Never was the individual citizen so marked down for hygienic attention as now. Statesmen vie with each other in schemes for improving his physique and giving him an equal mind, so valuable to the State is the contribution which in the last resort he, and he only, can make." One good result was a re-survey of the position from the national point of view, with a clearer vision than before. There was no doubt that in the past we had "let our bodies go, as it were; our civilization had literally gone to our heads, and our heads were not standing it too well either, for there were quite a lot of folk bothered by anxiety, fear, hopelessness, and odd tricks played by their nerves. So let's give the body a chance for a bit, and don't let us think we are wasting time in doing so."

The association's "brief," Lord Horder went on, included control of the whole range of physical measures of diagnosis, prognosis, and treatment which went conveniently by the generic name of physiotherapy. The range was very wide and included some of the most valuable agencies and methods

known to medicine. Into this group came skilled manipulation, massage, gymnastics, remedial exercises, balneology, and other forms of hydrotherapy, the application of light, heat, and cold in various ways, other kinds of ray therapy, and electrical methods. In all these matters the association could speak with authority, and if it did not "pull its punches" its influence would be incalculable. He warned against the temptation to play up to the public demand for the machine—the public thought an apparatus could not lie—or to give them the physiotherapist's equivalent of the bedside manner. The consideration of the spas and health resorts of the country also entered into this matter. The position which these had so far taken in physical medicine was unsatisfactory as compared, for example, with the use made of its spas by Soviet Russia. The State must be educated in the value of spa and health resort treatment in the prevention as well as in the cure of disease and in promoting the efficiency of the worker.

In the aetiology and treatment of chronic rheumatic diseases we had gone ahead with treatments in the absence of exact knowledge of causative factors (as also in cancer), or, the causative factors being known, we had lacked specific therapy (as also in tuberculosis). In the case of cancer it was really a form of physical treatment—namely, radium and x-ray therapy—which had brought relatively good results, and in tuberculosis also it was a series of physical treatments that had changed for the better the outlook for the chronic case.

Education of Profession and Public

Lord Horder went on to point out that the constitution of the new association stressed the importance of undergraduate and postgraduate training in the principles and practice of physical medicine, and it existed to encourage both of these. It also included a general clause in which it expressed as its aim the protection and furtherance of the interests of physical medicine. "We hold a brief for improving the status of the physical medicine specialist and for securing a diploma in physical medicine. The endowment of one or more universities would help us further towards attaining our aims than anything else that we could do." There remained the education of the community in the value of physical medicine—a big task, but one which must be undertaken. It included close co-operation with the educational authorities, the schools, and industry, keeping always in mind the doctors who advised these bodies and interests. These doctors should be invited to join in such discussions and the subsequent recommendations.

Certain aspects of physical medicine, Lord Horder concluded, had been markedly developed during recent years, as, for instance, radiology, which had staked out its special claim and taken its place within the hierarchy of medicine. This had grown to such dimensions that it could look after itself; but he recalled that he helped to nurse it in its infancy and stood by it in its tender years. The Chartered Society of Massage and Medical Gymnastics had developed into a corps of extremely proficient technicians, and he had for two periods occupied its presidential chair. It had also been his privilege to lead a group of colleagues in the formation of the Empire Rheumatism Council, a body which had produced a scheme for national action in the endeavour to solve the problem created by the series of crippling diseases due to rheumatism, and he was now chairman of the joint committee recently set up between that Council and the British Orthopaedic Association. Not all the causes of physical medicine which he had championed had been won. Now the British Association of Physical Medicine had been formed, and although he was president for its first year "the future of this association lies with you, and not with me, but I have faith that you will make that future a good success."

V. J. Birnberg and A. E. Hansen (*J. Pediatr.*, 1942, 21, 774), under the name of thrombophlebitis migrans, describe a rare clinical syndrome characterized by repeated venous thromboses occurring intermittently or concurrently, chiefly in the superficial veins in various parts of the body. Their case, which occurred in a boy aged 14, was the first recorded in a child. Heparinization failed to prevent further venous thromboses, and necropsy showed that death was due to mesenteric thromboses. Bacteriological examination gave no clue as to causation, but the presence of eosinophil inflammation and swelling of the intima of an involved vein suggested an allergic phenomenon.

Reports of Societies

DISCUSSION ON PENICILLIN

One of the largest meetings ever held at the Royal Society of Medicine took place on Nov. 9 for a discussion on "Penicillin" in the Section of Experimental Medicine and Therapeutics (the new name of the Section of Therapeutics and Pharmacology). The Barnes Hall was crowded out, and many stood during the whole three hours of the proceedings. Dr. R. D. LAWRENCE presided.

Early Experiments

Prof. A. FLEMING said that "penicillin" was the name he gave originally to an antibacterial substance produced from a mould. Mycologists knew many varieties of the fungus *Penicillium*, but only one of these, apparently, resulted in the substance known as penicillin. All the substance which had so far been made in this country derived from that early culture. He cultivated it in fluid medium, and found that the fluid under the mould had an antiseptic property which acted powerfully on certain micro-organisms, such as the haemolytic streptococcus and the gonococcus. He then tested it on leucocytes, because the antiseptics he had previously tested had a far greater lethal action on leucocytes than on bacteria; but that was not the case with penicillin. Nevertheless, the crude penicillin which he obtained in those early experiments was not very strong, early attempts at concentration were not successful, and, although it remained in the laboratory for certain purposes, its therapeutic use fell into abeyance until revived by the work of Florey and his associates at Oxford.

A warning was necessary that penicillin treatment should not be applied in infections by micro-organisms which were not sensitive to the drug; it was not a cure-all. Further, it was desirable to make tests of the bacteriostatic power of the blood to determine how much of the drug remained. It might be that good therapeutic results were obtainable with penicillin even when such a small dose was injected that by present methods no bacteriostatic power could be detected in the serum. Perhaps its most important use was locally in more or less minor infections, and not in the dramatic cases where patients were occasionally snatched back from death. The action of penicillin was bacteriostatic rather than bactericidal. With penicillin, as with the sulphonamides, the destruction of the organisms had to be largely by the tissue cells or blood cells, and therefore it followed that the best results would be obtained in patients who had the highest degree of immunity. Although in most cases brilliantly successful results were obtainable by penicillin alone, there were cases where immunological methods could help, just as with the sulphonamides. He added that as soon as the chemists discovered what the substance was and could make it, no doubt they would experiment with the molecules and produce a series of new preparations, some of them perhaps far stronger and with a wider application than the original penicillin.

Characteristics of Penicillin

Prof. H. W. FLOREY (Oxford) said that any credit for the Oxford work attached to the whole of a group of workers there, who, incidentally, were under no delusions concerning the discovery, and realized that a series of lucky accidents had led to the present position, although there had at the same time been a good deal of hard work. Pure penicillin would inhibit sensitive organisms in dilutions of 1:50,000,000 to 1:100,000,000, and morphological effects on the streptococcus were to be seen even to dilutions of 1:250,000,000. The sensitive bacteria included *Str. pyogenes*, *Staph. aureus*, *Str. pneumoniae*, *Str. viridans*, *B. anthracis*, and several others. Among those which did not give good therapeutic results was the bacillus of tuberculosis.

Chemical properties affecting clinical application were the stability of the salt between pH 5 and 7, its destruction by boiling, by oxidizing agents such as hydrogen peroxide, by the enzymes produced by some bacteria, and by heavy metal ions such as copper and lead. There must be neither acids

nor alkalis in any vessel in which penicillin was handled. These facts explained why the substance was so difficult to make. Its biological properties included lack of toxicity to mice and other animals. Leucocytes and tissue cultures were unaffected by solutions many times stronger than were required for bacteriostasis. It was little influenced by the number of bacteria present. It was not inhibited by pus, a matter which was of cardinal importance in explaining why results were obtained with it in purulent infections, nor was it inhibited by tissue autolysates or by blood or serum. It was excreted in urine (rapidly), in bile, and in saliva, but not in tears or pancreatic juice. It did not penetrate to the cerebrospinal fluid. Absorption was rapid from muscle and subcutaneous tissue and from the small intestine. It could not be given by the stomach because most stomachs contained acid, but by the rectum on account of bacteria.

Methods of Administration

It was clear from animal experiments, Prof. Florey continued, that it would have to be given by certain indicated routes. It could be given continuously intravenously or intermittently intravenously, and the dosage on which they worked was 15,000 units every three or four hours. Penicillin was one of the few drugs—indeed, he did not know of other—with which it was not necessary to worry about excretion. With the sulphonamides one had constantly to consider whether one was getting to the toxic level, but with penicillin an overdose offered no terrors, and as time went on and more penicillin became available, if the chemists rose to the occasion, they would have to beware of trying to work minimums, because they were bound to give not enough some time or other. Inadequate dosage was a real danger. Another factor to be remembered was the possibility of having an inactivated penicillin as the result of the presence of a strain of organisms which, though belonging to the sensitive species, was in fact an insensitive strain. One worker had said that about 4% of staphylococci encountered were penicillin-resistant. In local administration there must be adequate access to infected parts, and this depended upon surgical technique which was the main problem in the use of penicillin at present time. Sustained application must be made, for it was fairly rapid absorption. What looked like a great effect of penicillin would quickly diffuse into the infected tissues.

Penicillin in the Treatment of War Casualties

Prof. Florey went on to say that he recently had the opportunity of going to North Africa and using penicillin in co-operation with ten surgeons in that theatre of war. They tried to do as well as to sew up infected wounds and fractures, giving penicillin to prevent sepsis. He showed a film taken in North Africa and the Middle East illustrating the treatment of war wounds by this method. Out of 171 cases so treated, complete union was obtained in 104, subtotal union in 60, and failure in 7. The film showed the operation, the first cleaning of the limb with soap and water, the trimming of the skin edges and muscle, the insertion of tubes, and closing of the wound, to the instillation of the penicillin, which in a number of the cases was repeated twice daily for five days. The stitches were removed after ten days, and in many of the cases, as illustrated on the film, the patient showed excellent recovery with a good usable limb about 24 days after treatment or 28 days after the infliction of the wound. In some cases penicillin was used with sulphanilamide powder and the mixture blown on to the wound. Stress was laid on the necessity of an efficient blower to secure good distribution of the powder with the minimum of wastage. In the case of one dirty wound treatment was by insufflation of powder for four days, another the patient was given 500,000 units of sodium penicillin parenterally. In the case of a septic stump a similar dose was given over five days. In certain cases the penicillin-sulphanilamide mixture was inserted locally at the clearing station, and afterwards at the base hospital 500,000 units of penicillin parenterally were given.

The PRESIDENT at this point asked for a definition of unit of penicillin. Prof. Florey replied that the unit was purely arbitrary amount of material which had been chosen for the very early days for experimental purposes.

Vehicles for Penicillin Administration

Flight Lieut. D. C. BODENHAM (R.A.F.) described some experiences at an R.A.F. hospital in the treatment of localized streptococcal and staphylococcal infections by direct applications of penicillin. He said that certain conditions responded extremely well to very small doses; other conditions responded poorly by the methods at present available for local treatment. As for the preparations of penicillin which could be used for these different types of wounds, the calcium salt supplied to him had varied in potency from 6.8 to 163 units per milligramme, and the daily application of only 4 units per sq. cm. of granulating surface could be effective. Some method of diluting penicillin became necessary, and three methods had been adopted. The first was a simple solution of penicillin dissolved in water, and for practical purposes the strength had varied from 100 to 500 units per c.c.m. Then the need arose for a powder which could be applied with an insufflator to the wound. A neutral diluent was wanted, and the choice was made of sulphanilamide prepared in powdered form. The preparation consisted of mixing with the sulphanilamide a 5% light magnesium oxide. This could be autoclaved at 5 lb. pressure for 15 minutes. When cooled it was shaken with penicillin powder to give a final strength of the penicillin and sulphanilamide mixture of 1,000 units per gramme. Another preparation was ointment which could be applied to the granulating surface. For this purpose lanette wax 33%, vaseline 33%, and water to 100% were taken. This could be autoclaved at 10 lb. pressure for 20 minutes. When it was cooled the penicillin solution, prepared beforehand in the strength of 500 units per c.c.m., was mixed with it, and the emulsion state was retained. One important point about this emulsion was that it was an oil-in-water emulsion in continuous phase. The consistency of it could be altered by simply adding more and more water. It was easily mixed with penicillin, it would adhere to a wet surface, and could be easily removed with water alone. The strength which had been used for most of the infected surfaces had been 100 units per gramme. For success in all these conditions the penicillin must gain access to every part of the wound all the time. That might be beyond the scope of the technique in some cases, but unless it could be achieved success was not likely.

Types of Wound Suitable for Treatment

Flight Lieut. Bodenham, continuing, said that in treating a large number of cases it became obvious that if the greatest good was to be obtained some chart should be prepared from which the salient observations could be made and rapidly recorded. It was necessary to know what was the type of wound, its cause, and what time had elapsed since it was inflicted. The cases which Prof. Florey had illustrated had been fairly recent ones; many of his own series came late, after other methods had first been tried. The earlier these cases were treated the less penicillin was needed and the better the result. It was necessary also to know the nature of any previous treatment, the type of organism, and the type of surface discharge.

In surface wounds such as burns the treatment used had been the application of 100 units of penicillin cream per gramme every 24 or 48 hours. The response had been good, negative swabs being obtained after four or five days. This was the most successful of the groups. In so-called "gutter" wounds penicillin cream had been applied to the amount of 100 to 200 units per gramme. In severe infection penicillin powder applications might be made every 24 hours. A wound measuring 10 in. by 2 in. and 1½ in. deep required 7,000 units per day. Powder could be applied to the wound and solution to the pockets, but the latter were a difficult problem. In sinuses the treatment was to give penicillin solution through a catheter passed to the limit of the track, the solution being 250 units per c.c.m. The injection should be sufficient to fill the track every four hours. Quite obviously in these more complicated wounds penicillin alone could not be expected to heal them when other factors, such as fibrotic cavity walls, were playing a part. The treatment of cavities turned largely on whether they were dependent or inverted, as the former would hold fluid. Penicillin solution was given through a catheter, 100 to 250 units per c.c.m., and 10% of the volume of the capacity of the cavity should

be given every four hours. The bacteriological response was good; the clinical result depended upon various other factors and was sometimes disappointing. The most difficult problem was the complicated cavity occurring in infections of joints, multilocular empyemata, and the like. Here the response to local treatment, even in large doses, was poor. Two cases of acute arthritis of the knee (staphylococcal) had 10,000 units per day for 15 days, but the result was poor. Complicated cases could not be expected to respond to penicillin alone, and surgery must be used to convert such cases to one of the simpler types in which penicillin was effective.

American Army Experience

Col. ELLIOTT C. CUTLER (U.S.A.M.C.) described four cases of severe fracture—in three of them of the femur and in the other of the tibia and fibula—which had received an instillation of 10,000 to 20,000 units of penicillin in solution when treatment was started. But in spite of continuous intramuscular applications of penicillin the presence of gas-forming organisms was detected in the wound after three or four days, and in all these cases the limb had to be amputated. Large amounts of penicillin were again applied intramuscularly—in one case 20,000 units every three hours until the patient received 1,000,000 units—and in all cases the condition after amputation was satisfactory and the patients had remained well.

In reply to a question as to whether the penicillin had any effect at all upon the gas gangrene, Col. Cutler said that they all felt that it had played a major part in survival. His own opinion was that anti-gas-gangrene serum was not very efficacious.

Major J. N. ROBINSON (U.S.A.M.C.) described an experience in treating sulphanilamide-resistant gonorrhoea with penicillin. The series of cases numbered 95, and in nearly all of them the penicillin was given intramuscularly to a total of 100,000 units. Of these cases 93 were cured at the end of one course of treatment, another was cured after a second course, and the last one did not respond to two courses and was considered a failure. Treatment was also tried in three cases of gonorrhoeal arthritis, one of which was successful after 200,000 units of penicillin had been given intramuscularly—15,000 units every three hours—but the other cases, which received only 100,000 units, were not cured. There were no toxic manifestations. The first 30 cases had been followed up and showed no evidence of recurrence or urethral discharge.

Further Clinical Trials

Mr. R. VAUGHAN HUDSON (Middlesex Hospital Penicillin Research Committee) described an investigation on 33 cases chosen because they were penicillin-sensitive as compared with an equal number chosen chiefly because they were insensitive. One method of treatment did not necessarily avail in all the stages of infection. It was in the case of the open wound that the issue was so complicated by the depth of tissue involved and the alteration of blood supply due to trauma. They had learned that a wound might be sterilized but would not heal if the blood supply or local metabolism was insufficient, and, alternatively, in the face of a good blood supply and lowering of the bacterial count, a wound would heal in spite of the fact that it was not completely sterile. As soon as infection was controlled, structure being adapted to function, early movement would improve the blood supply and hasten repair. Penicillin broke the link between the mobilized tissue and the dead tissue, so that by the systemic route with quite a short term of dosage the slough would separate, and proteolytic action of the contents of the tissue fluid would fragment it and enable it to be easily removed. The dosage for this purpose was somewhere between 100,000 and 300,000 units by the systemic route administered every three hours.

Prof. R. V. CHRISTIE (Hill End Hospital) said that during the past six months 117 cases had been treated in his department with penicillin, 104 by local and 13 by systemic administration. In a group of 34 patients with infection of bone, 14 were cured after penicillin administration. The administration was in some cases combined with surgical treatment, but whenever such treatment was performed it was shown that the identical operation was unsuccessful without penicillin. Of the remaining patients 13 were improved and 7 unaffected. In only three of these cases had the duration of infection been less than

one month. The presence of a sequestrum was not in itself a contraindication to penicillin therapy, but the results were not so good as in cases without sequestra. In the group of infections of the soft tissues 44 cases were treated, 23 being cured and 10 improved. Those having a duration of less than one month obviously responded better than those of longer duration. He also mentioned the use of penicillin in certain skin conditions. Excellent results had been obtained in some cases of impetigo.

Lieut.-Col. J. S. JEFFREY said that in the surgical treatment of these wounds penicillin very quickly dealt with the Gram-positive pyogenic organisms, but they were still left with the Gram-negative, which resulted in Gram-negative pus in considerable amounts. When the wounds were sutured up closely this might collect in the dead spaces and cause trouble; therefore where there was danger of a dead space it was thought better to leave the centre of the wound open. He also mentioned rather disappointing results from giving penicillin alone in cases of gas gangrene. In gas gangrene the necrotic tissue was no longer getting an adequate blood supply, and therefore the penicillin was no longer being carried to that part. Nevertheless, there was absorption from that necrotic part, and therefore anti-gas-gangrene serum should be given.

Mrs. FLOREY gave an account of some work in which penicillin had been used in generalized infections, chronic sinuses, abscesses, arthritis, skin infections, infections of the eyes and lips, empyemata, acute mastitis, and acute infections of the hands—a miscellaneous collection of separate clinical entities. From the biological point of view they had been chiefly staphylococcal infections. Out of rather over 300 cases 250 had shown complete recovery, 41 had improved, and in 14 no change had been registered. She showed some photographs illustrating the restoration of function in hands following treatment of the infection by penicillin. There were rapid relief of pain and disappearance of swelling, but the restoration of function was the most striking of the differences. The cases included palmar sepsis and tendon-sheath infections which had been successfully treated.

The report of the 1942-3 session of the Royal Academy of Medicine in Ireland states that the attendance at sectional meetings was well maintained, and the Council notes with pleasure the increased interest shown by Fellows in the Section of State Medicine. Dr. T. Percy C. Kirkpatrick, who signs the report, includes memorial tributes to two Honorary Fellows of the Academy—Howard Atwood Kelly, professor of obstetrics and gynaecology at Johns Hopkins, and George Washington Crile, professor of surgery at Cleveland; also to three ordinary Fellows, Dr. William Boxwell, Dr. J. C. Mant Martin, and Sir William Ireland de Courcy Wheeler. A year ago the Council of the Academy, at the request of the Sections of Medicine and of Surgery, appointed a committee to consider the outbreak of anterior poliomyelitis which had lately been reported in various parts of the country. The committee, under the chairmanship of Dr. C. J. McSweeney, found that 364 cases of the disease, or 12 per 100,000 of the population, had been recorded. The mortality varied from 41% in County Clare to 28.8% in Cork Street Fever Hospital, Dublin. The report put forward valuable recommendations for dealing with future outbreaks of poliomyelitis, and urged that the Department of Local Government and Public Health should organize, among its chief medical officers, a body prepared to deal at once with the disease should it again appear in epidemic form.

The annual general meeting of the Association of Industrial Medical Officers was held at the London School of Hygiene and Tropical Medicine on Oct. 16. The chair was occupied by the retiring chairman, Dr. M. W. Goldblatt, who reviewed the work of the association during the past two years, and spoke of the part that he hoped industrial medicine would play in the future reorganized medical services. In proposing Dr. J. C. Bridge, C.B.E., as the next chairman of the association, Dr. A. J. Amor spoke of the honoured place which Dr. Bridge occupied in the world of industrial medicine. Dr. Bridge was elected with acclamation. Dr. W. Blood was re-elected as hon. secretary and Dr. S. A. Underwood as hon. treasurer. At the afternoon session Dr. M. W. Goldblatt read a paper on "The Investigation of Toxic Hazards," and discussion followed.

At the annual general meeting of the Association of Anaesthetists of Great Britain and Ireland held on Oct. 23 the following officers were elected for the ensuing year: President, Brigadier Ashley Daly, R.A.M.C.; Vice-President, Dr. C. Langton Hewer; Hon. Treasurer, Dr. Z. Mennell; Hon. Secretary, Dr. A. D. Marston.

Correspondence

Some Therapeutic Fallacies

SIR,—I was much interested in the article on some therapeutic fallacies (Nov. 6, p. 572), and I hasten to respond with my own views as a general practitioner.

Regarding the question of essential hypertension, I can disagree that the patient should not be told; otherwise making too light of the matter, the seriousness of the condition will not be fully appreciated. It certainly is not necessary to over-estimate the danger of the condition or to alarm the patient unduly. If one just states that the blood pressure is on a high side, and the patient should take things quietly and see a doctor, say, once a month, then much will have been achieved. It must be remembered that Drs. Linnell and Thomson are such patients from a consultant's point of view, but it is a general practitioner who is called suddenly late one day, to find such a patient develops a stroke while engaged at a laborious task during his work, or, as has been my experience on the golf course. In so far as treatment is concerned, I agree that there is no specific therapy, but diet in the obese will contribute much to the patient's well-being. A repeated blood-letting at frequent intervals will often relieve unpleasant symptoms.

I endorse the remarks on arteriosclerosis and angina pectoris and also on the use of digitalis. This drug is probably more frequently abused than even the sulphonamides. I consider digitalis a dangerous drug in inexperienced hands, and sooner the newly qualified practitioner learns to appreciate its use the better. I should imagine the amount of digitalis used in this country must be appalling. In those cases where Drs. Linnell and Thomson mention as benefiting from digitalis therapy its use is invaluable.

Anaemia is a condition which requires the utmost consideration. Why prescribe iron *ad lib.* to a patient who is regarded as being anaemic on no grounds other than an examination of the conjunctivae? But how many general practitioners are as fortunate as we in Kingston in having good laboratory facilities easily and cheaply available? It is safer to give iron to the non-anaemic patient than to withhold it from the one who needs such treatment. This raises the fundamental question of co-operation between the laboratory, indeed all ancillary diagnostic services, and the general practitioner. The foregoing remarks apply in great measure to the use of the sulphonamide group of drugs. Until the general practitioner is able to determine the cause of infection scientifically the abuse of sulphonamides will continue.

I am disappointed at the remarks made on the use of expectorant mixtures. Do Drs. Linnell and Thomson seriously believe that I can satisfy my chronic bronchitis by telling them to hang over the edge of the bed and cough? Bronchiectasis this treatment may seem reasonable, but in every patient seen by the general practitioner develops bronchiectasis. I have found the average patient with chronic bronchitis as a rule obtains much relief and comfort from simple alkaline expectorants. So far as their use in lobar pneumonia is concerned, when there is associated bronchitis their value has been well proved.

I am in whole-hearted agreement on the subject of constipation. Much harm has been caused by the highly exaggerated advertisements tending to make one feel "bowel-conscious." The treatment of constipation begins with the mother, and can do much by withholding purgatives and training her child into regular habits. A good mixed diet with plenty of fruit and regular exercise are all that are needed for the normal person. It should, however, always be remembered that constipation is often the first symptom of serious disease, and a complete investigation should always be undertaken.

In conclusion, may I express my appreciation to Drs. Linnell and Thomson for their very interesting observations. I am, etc.,

Kingston-on-Thames.

M. H. FRIDMAN.

SIR.—A more depressing exposition of the doctrine of therapeutic nihilism can scarcely have been written than the contribution under the above heading in the *Journal* of Nov. 6; and yet, with the experience of years, one has to admit that much of it is true. Such being the case it is clear that medical textbooks need revision in great part, and equally manifestly teachers of medicine should not exceed the age of about 3, for only thus can it be ensured that the stream of medical instruction will remain pure and undefiled by the babbling inaccuracies of dotards.

While they become almost lyrical about the "beautifully aligned rhythmic movements" and so on of the intestinal anal, the writers, in their suggested treatment of constipation, re all in favour of the *vis a tergo* rather than the *vis a fronte*. But what, after all, can be more unnatural, more unphysiological, and, in most cases, more unnecessary than an enema? One of my teachers used to say, with an air of considerable disdain for the constipated, "All you want is a little marmalade for breakfast." "Shades of colocynth, jalap, and gamboge! Just little marmalade for some of our 'chronics'!"

The fact of the matter is that there is more egregious nonsense written and talked about constipation than about anything else, and usually by doctors. When someone discovers that there is to know about Auerbach's plexus then the hidden mystery of constipation may be revealed. As yet constipation is merely the happy hunting-ground for lectures by the dogmatic and the cranky inside the profession and by manufacturing chemists outside. Sophistication, however, in medicinal treatment is not exclusively the property of people of the calibre of the writers, and a sound critical attitude towards remedies and their effects is not unknown among practitioners.—I am, etc.,

Hore.

G. L. DAVIES.

Vitamin B Deficiency

SIR,—I was very interested in the article on vitamin B and psychological disorders (Oct. 23, p. 503). For a long time I have found vitamin B particularly useful in psychological states, but my experience, in contradistinction to that of your observers, has been more of its use in psychotic states associated with defective nutrition and absorption, and also in alcoholic patients. Your contributors stress that a certain amount of psychological disturbance, perhaps principally psychoneurotic, is attributable to deficiencies in the amount of vitamin B in wartime diet, and that this, combined with the stresses and strains of these times, precipitates symptoms. I feel that this may well be so, and the authors make a strong case, but in addition I would suggest that there is a by no means inconsiderable number of patients who, where no deficiency in vitamin B is present, seem nevertheless to require amounts of this vitamin considerably in excess of the normal. My own feeling is that there is a definite relationship between the central nervous system's requirements in vitamin B and the amount of intellectual work, whether or no this latter be accompanied by stress, accomplished by the individual.

We should not forget that some of the toughest stocks in Europe—say, our own Highlanders and Norwegian fishermen—live habitually on a diet in which the content of vitamins B and C is very low. It can be argued that these people as a whole show no very marked signs of vitamin deficiency. They are, however, living natural lives, whereas in our grossly urbanized communities a large number of the population are in what one might call occupations requiring mentation as much as manual work. As these accessory factors are necessary for the oxygenization of carbohydrate for the nutrition of the central nervous system it does not seem too far fetched to postulate that, apart from any question of stress or strain, the brain in more constant use requires more vitamin B than that of those engaged in more natural occupations.—I am, etc.,

Bath.

A. GUITDHAM.

Retention of Urine and Pyelitis in Girls

SIR,—I hope you will kindly allow me space to air these comments on a detail affecting the health of young children in schools.

Recently I have had a girl of 7 under my care. She was acutely febrile, running a temperature of 104.5° for the first two days, and complained of abdominal pain and headache.

The condition proved to be an acute pyelitis, and under treatment with sulphanilamide and a citrate mixture subsided in a week. A chat with her parents elicited a fact which gave me a clue to a possible cause for the condition. The child herself, an only child, was exceptionally well cared for, and the home spotlessly clean and tidy. I was informed that the little girl had come home from school on a number of occasions with wet underclothes. It was stated with conviction that the schoolmistress was in the habit of refusing permission to children to leave the classroom to perform natural excretions. This child had either been frequently refused, or, being nervous, was afraid to ask permission to leave the classroom.

Now, although I am aware that pyelitis is not uncommon in young female children, it struck me that here was at least one reason why this is so. One can readily imagine the train of events following a series of enforced retentions of urine in a full bladder. Slight infection is caused by the first few efforts at retention; further infection is facilitated by the wearing of a wet and soiled undergarment; and later attempts at retention of the contents of a full and infected bladder easily lead to infection of the renal pelvis.

Conversation with other parents of young children (I have two of my own) leads me to believe that this repressive attitude is fairly common among schoolmistresses having charge of youngsters. In my view this habit is both unfeeling and dangerous to health. It may be argued that children are expected to relieve themselves conveniently at playtime. But young mites can easily forget, or may not feel the urge at the exact time. They are then afraid, if the teacher has been known to be severe on the matter, to mention their desires, and attempt an uncomfortable and possibly dangerous retention. It should, in my view, be the proper part of a teacher to invite children to run out and empty the bladder or bowel if they feel the need, or if they have missed doing so at playtime or other recess. If school authorities have not issued any instructions to teachers on this matter, it should be time that they did wherever young children of tender ages (say, up to 9 or 10 years) are concerned.—I am, etc.,

Birmingham.

C. C. GRAYSON.

Septic Hands and Fingers

SIR,—Your recent correspondents on the maltreatment of septic fingers appear to agree on one point only—they all blame the poor general practitioner for their bad results.

A small proportion of septic fingers starting as deep-seated infections—either subperiosteal (blood-borne) or deep pulpar (implanted or blood-borne)—will cause local damage and destruction of tissue with ultimate slough separation in spite of early and expert surgery.

The warning of the misuse of hot fomentations is justified. Stress should be laid on the damaging effect of using oiled silk (now supplanted by oiled paper in the N.W.F.). This is probably more responsible than any other factor in the production of the horrible soggy lifeless skin so often seen. Unfortunately home-nursing books and lecturers still appear to advocate its use.—I am, etc.,

London, S.W.16

HARRIS AVERY.

Financial Allowances in Tuberculosis

SIR.—The recently introduced Government scheme of monetary allowances for tuberculous subjects has, not unnaturally, attracted widespread interest, not only in medical but also in lay circles. The recent correspondence in the *Times*, initiated by a tuberculous patient, raises points of significance and interest to readers of both lay and medical press, concerning, as it does, all occupied with the control of tuberculosis.

Three of the prerequisites for the control of tuberculosis are: (1) early diagnosis, vastly stimulated by the recently introduced mass radiography service; (2) early treatment, which involves convincing the patient, frequently the bread-winner, of the absolute necessity for accepting prolonged treatment in a sanatorium with the minimum delay; (3) prevention of the spread of infection to family contacts. Hitherto the overriding social and economic problems confronting the patient have militated, not unreasonably, against his accepting medical advice. Those of us closely connected with chest clinics and sanatoria,

and faced with this constantly recurring dilemma of the patient, can fully appreciate the human problems and hardships involved.

The Government scheme of financial allowances seemed to indicate the fulfilment of long-cherished hopes and a great advance in the direction of alleviating such problems, but those of us who attended the recent conference of the National Association for the Prevention of Tuberculosis heard with mixed feelings the Minister of Health expounding the scheme, and many criticisms from authoritative sources were raised regarding (1) the inadequacy of the allowances, and (2) the discrimination between the early and the chronic, the pulmonary and non-pulmonary case. The purpose of the scheme is to enable men and women to undergo treatment without financial hardship to themselves or their dependants, but previously many progressive authorities, with one of which I am intimately connected in a consulting capacity, have, through public assistance and social welfare departments, made allowances not infrequently higher than the present Government ones. In addition, personal contact between tuberculosis workers and the local departments has made possible special treatment for certain individual cases of hardship. The distinction between the two categories of patients leads to the chronic—who is not necessarily incurable, even though his cure may not be sufficiently complete to enable him to return to whole-time war industry—falling into a state of despondency with a personal grudge against his tuberculosis physician and against social workers. Such an attitude, engendered perhaps by a misunderstanding of the scope of the Government scheme, renders co-operation yet more difficult, and brings to naught suggested plans of vocational guidance and rehabilitation, designed to make even the partial invalid a useful citizen.

It is therefore to be hoped that the widespread and genuine apprehension felt will be allayed by a complete review by the Minister of Health of the scale of allowances for tuberculous patients, and that these allowances will be extended not only to a wider group of sufferers from this disease but also, may one venture to hope, where similar circumstances apply to other forms of chronic invalidism, such as, for example, rheumatic, cardiac, and other pulmonary diseases. The financial burden of any such scheme will be considerably reduced, taken as a long-term policy, if the actual allowances which enable the patient, freed from economic and therefore mental anxiety, to undergo adequate treatment in a proper spirit of co-operation are followed by schemes of industrial training and subsequently protected or full employment.—I am, etc.,

London, W.1.

PHILIP ELLMAN.

Institutional Provision for Mental Defectives

SIR,—I was interested in Dr. M. Greaves's letter (Oct. 30, 1959). The position in Halifax is that we have a fairly long list of mental defective cases awaiting institutional accommodation. The general national position appears to be that there are about 17,000 imbecile and idiot children and 84,000 adult defectives in need of institutional care. The total incidence of mental deficiency is at least 320,000. It is clear that the number of defectives is so great that for many years to come it will be impossible to provide an adequate amount of institutional accommodation. I hope mental deficiency will be labelled as a "priority" on the post-war planning and reconstruction blue-prints. Although the prevention and control of the disease will never make a good political vote-catching device the matter is one of extreme social importance. —I am, etc.,

Halifax.

G. C. F. ROE,
Medical Officer of Health.

Infectious Mononucleosis

SIR,—Halcrow, Owen, and Rodger's excellent article on the subject (Oct. 9, p. 443), which will certainly widen our views on the frequency and epidemiology of the disease, draws attention to the difficulties in differential diagnosis. It may, indeed, be impossible in the early stages to differentiate the condition from German measles, especially if blood counts are done before the typical mononucleosis has developed.

In a woman aged 36 who fell ill with high temperature and developed enlargement of the lymph glands in the posterior

triangle of the neck, the total white cells were 6,800 and differential count showed no eosinophils, 60% polymorphs marked shift to the left (21 stab forms out of 60), lymphocytes, some of them atypical, and 9% monocytes. 3% Tüirk cells were also found. Pyrexia, swelling of lymph glands, and blood picture were very suggestive of rubella. However, the rash which I predicted did not appear and pyrexia continued. The differential count a week after onset had changed to 26% polymorphs (5% stab forms) and mononuclear cells, many of which were atypical and contained nucleoli. This clinched the diagnosis of infectious mononucleosis, which was then proved by a positive Paul-Bunton test.

Similar findings have not been infrequent. To complete matters, H. J. Templeton and R. T. Sutherland (*J. Amer. Med. Ass.*, 1939, 113, 1215), who observed skin eruptions in 17 of 91 cases, have stated that in 12 of the 17 cases the rash was indistinguishable from German measles.

In the case mentioned a trial was made with sulphathiazole which produced immediate fall of temperature and rapid improvement of clinical symptoms. This is in contrast to the experiences of Halcrow, Owen, and Rodger, who used sulpyridine, but Hoffman, Lees, and Comros (*Amer. J. Med.*, 1942, 203, 731) recorded prompt improvement in all the patients after sulphathiazole, while their previous experience with sulphanilamide were disappointing.—I am, etc.,

London, W.1.

H. UCKLES.

Sulphonamides in Otitis Media

SIR,—I think a warning should be given as to the use of sulphanilamide and its relatives in acute otitis media. I have used it freely myself and have seen no ill effect in these cases, but if the membrane is bulging when I see the patient I have invariably performed a myringotomy before starting treatment.

I have, however, been sent on account of deafness a number of patients, mostly children, who, having had pain in the ear for two or three days, have been put on treatment and have never discharged. When I have seen them some four weeks later the membrane has been bright but adherent in whole or part and the child very deaf. Even in older children, where I would permit catheterization of the Eustachian tube, I have usually been unable to improve the hearing. I believe that in these cases are those in which an effusion has occurred and has dried up without perforation of the membrane on administration of sulphanilamide. I believe that they can be avoided if the sulphonamide is not administered to a child with a bulging drum without a myringotomy being performed at the same time. The disaster does not seem to occur in cases seen extremely early when the membrane is only flushed and not bulging, nor in cases in which a discharge has already begun when the sulphonamide is administered.—I am, etc.,

Northampton.

E. BROUGHTON BARNES.

Precision Cephalometry and Pelvimetry

SIR,—Dr. Millington (Oct. 16, p. 495) points out that with a lateral tube-shift a knowledge of the tube-film distance is unnecessary. A useful table of correction factors for each millimetre of the shadow-shift from, say, 10 to 30 mm. with a 3-in. tube-shift may be quickly compiled, the formula being

$$\frac{T}{T+S}$$
 (T being the tube-shift and S the resulting shadow-shift), and this greatly curtails the calculations. Such a large error as half an inch in the tube-shift results in an error in the calculated result of about one-tenth of an inch, not a very large discrepancy with such a mistake, and proving the accuracy of the method if the distances be carefully adhered to.

However, if all calculations are to be avoided and the work greatly shortened, the use of a chart (as described in the *British Journal of Radiology*, April, 1942) is required. In this case a knowledge of the height of the diameter above the film is necessary, and for this the tube-film distance must be known and must be constant, a convenient distance being 30 in., which is, moreover, the optimum distance for the Potter-Bucky diaphragm. Also for the antero-posterior diameter, i.e., the conjugate and pubo-sacral—in the lateral film, the

here is no tube-shift, a knowledge of the distance is imperative, and the height of the diameters above the film has to be measured. This can be accurately determined by a measurement of the over-all width of the great trochanters with a calliper, the patient being then turned on to her side into such a position that the measurement of the cleft of the buttocks to the table is equal to half the width of the great trochanters, which with the addition of the distance of the table top from the film gives the height of the diameters above the latter. This method also ensures the superposition of the great trochanters and brings the diameters truly parallel to the film.

A point which does not seem to be generally appreciated is that, provided the diameter to be measured is parallel to the film, the position of the tube in its horizontal plane is unimportant. It may be moved to any position in the same plane and suitably tilted so as to project the diameter on to the film, and the measurement of the projection will remain unaltered the ratio of the tube-diameter distance to the diameter-film distance remaining constant, and the correction factor therefore constant. This requires to be stated, as a recent paper on this subject said that if the tube be centred over the conjugate diameter and the same correction factor be applied to the more distant pubo-sacral diameter, a false computation of the latter will be obtained. Ocular proof that this is not the case may be readily furnished by taking two films of a penny placed at a height of 5 or 6 in. on a cardboard box parallel to the film, one with the tube centred directly over the coin and the other with the tube at a considerable distance, say 12 in., in the same horizontal plane and suitably tilted, when the projection of the image of the coin in the two films will be found to be identical in all respects with no distortion.

The only measurement for which accurate centring of the tube is necessary is for the oblique diameters which are at an inclination with the film, when the tube must be accurately centred in the midline over a point midway between the plane of the anterior-superior spines of the ilia and the symphysis pubis. The calculation here is considerably more complicated, and perhaps of less importance except in special cases (*vide* the paper already cited).

The most valuable measurement is the determination of the inlet and outlet in square measure (square centimetres), which may be said generally to determine the advisability, or the reverse, of Caesarean section. The measurement of the foetal head presents more difficulty as it is seldom that the occipito-frontal or suboccipito-bregmatic or the biparietal diameters are in a plane parallel to that of the film. However, this measurement is of less importance. Gross abnormalities—as hydrocephalus—are immediately apparent; otherwise the variations are not very great, and the head is a malleable object able to adapt itself by moulding within fairly wide limits to the shape and size of the rigid pelvis.

It is to be hoped that the discussion has shown that x-ray pelvimetry has a very real value in obstetrics—a matter upon which doubt has recently been cast in some quarters.—I am, etc.,

Newport.

W. H. HASTINGS.

Epidemiology of Weil's Disease

SIR,—The article of Capt. S. Varadi (Jan. 30, p. 126) and the letter of Dr. K. Blum (Feb. 20, p. 231) on Weil's disease prompt me to draw attention to some recently emphasized knowledge concerning the epidemiology of leptospirosis, and to suggest that this knowledge might be useful when attempting to trace the source of infection in certain cases of Weil's disease.

At least two types of pathogenic leptospirae (*L. pomona* and *L. mitis*) are known to be endemic in pigs and cattle in the coastal district of South Queensland,¹ and all of our cases have had contact with one or other of these animals. In 1939–40 a serious outbreak of classic Weil's disease, with several fatalities, occurred in Western Samoa, a mandated territory of the Dominion of New Zealand. Investigations performed in Brisbane showed that the disease was heavily endemic in Samoan pigs.² Many of these patients were probably infected after contact with pigs. No work has yet been done to ascertain whether *L. heterohaemorrhagiae* exists in Australian pigs, but in view of the fairly high incidence of leptospirosis in imported rats (especially *Rattus norvegicus*) in Brisbane,³ it is possible

that the disease may be present in piggeries situated near urban areas.

These facts may not be well known to the profession in Britain. I feel, however, that they are of sufficient interest and importance to justify intrusion on your space in time of war, for it may well be that farm animals in Britain also can act as carriers of the disease.—I am, etc.,

Brisbane.

Disappearance of Breast Cancer with Stilboestrol

SIR,—The following report of the disappearance of primary and secondary breast cancer with stilboestrol seems worthy of note.

A married woman aged 62 was seen by me in January of this year with a hard lump in the left breast adherent to the skin and clinically a typical case of scirrhous carcinoma. She also complained of a lump in the left axilla which she had noticed for four months. She looked pale and had lost 3 st. in weight. I sent her to see our consulting surgeon, Mr. E. K. Martin, at the Wembley Hospital, who confirmed the diagnosis and advised operation. Her weight then was 7 st. 4 lb.; haemoglobin 76%; x-ray examination of chest showed fibrosis only; the liver was palpable.

She was operated upon by Mr. Martin on Feb. 1, a left radical mastectomy, but removal of growth in the axilla was incomplete owing to attachment to the brachial plexus. The breast and axillary tumour were sent to the Bland Sutton Institute of Middlesex Hospital for examination. The pathological report was: "Carcinoma of breast; growth is a spheroidal-celled carcinoma; there is one large deposit of similar growth in the axilla." She was in hospital for five weeks and her convalescence was slow. It was intended to send her elsewhere for deep x-ray therapy, but her condition gradually worsened and she was never fit for it.

On July 22 she was again seen by Mr. Martin, who reported extensive recurrence on skin, scapular region, and posterior triangle. It was decided to administer stilboestrol. Her weight then was 6 st. 9 lb.

Her health gradually improved, the tumours slowly disappeared. I was so gratified with the result that on Oct. 21 I sent her to see Mr. Martin again, who confirmed there was nothing to be seen or felt in the posterior triangle, skin, or scapular region. She has gained 16 lb. in weight; haemoglobin 95%. She now looks well and does her own housework. It appears to be a cure. The dose of stilboestrol has been quite small, 0.5 mg. daily for three periods of twenty-four days. She has also had iron by the mouth. The acid serum phosphatase has not been estimated but it is intended to do this.

I am grateful to Mr. E. K. Martin for his permission to publish these notes and also to the Bland Sutton Institute for doing the pathological work.

—I am, etc.,

Wembley.

R. TUDOR EDWARDS.

Treatment of Lupus Vulgaris

SIR,—The recent completion of five years' work by the three Finsen-Lomholt lamps installed by Glasgow Corporation at Baird Street Hospital, Glasgow, gives us an opportunity to review our experience of these lamps.

In that period 103 lupus patients have had treatment, the number under treatment in any particular year varying from 75 to 86. Twenty-two patients are quite free from lupus nodules at present and are probably healed. Forty-eight patients are regarded as having markedly improved, and of these about half are nearly healed, there being only odd nodules present in their scars. Twenty-two have improved to a less degree. Ten patients have had insufficient treatment to enable an estimate of the result to be made. One has died from a complicating epithelioma. In all 21,608 hours of treatment have been given, and the number of individual attendances has been 12,588.

The clinic is in operation on two days a week from 9 a.m. to 5 p.m. and on three days a week from 9 a.m. till 8 p.m. Every endeavour is made to arrange suitable times of treatment for workers, and a large proportion of our patients are in employment. One nurse is in charge of three lamps. Servicing is carried out by the corporation electricity depart-

ment. About 15% of our patients come from surrounding local authorities.

We are particularly interested in Dr. Arthur Burrows's letter (Oct. 2, p. 432), in which he implies that 20 minutes is commonly an average exposure time for one treatment. Our experience has been that nothing less than one hour is satisfactory.

As regards plastic surgery, we are endeavouring to make use of the facilities in the emergency hospitals of the Department of Health for Scotland. We are in very close co-operation with the local radium institute for treatment of patients in whom malignancy supervenes. We have tried as much as possible to reserve this method of treatment for face cases, because of the soft pliable nature of the scar which is left—a great advantage as compared with former methods of treatment.—We are, etc.,

Glasgow.

S. I. A. LAIDLAW.
A. MACLEAN.

Regional Anaesthesia

SIR,—I have just read the annotation on regional anaesthesia (June 5, p. 700), and hope to be allowed to submit this criticism.

1. Is it correct to say that "one may assume that unconsciousness during surgical operations would have been welcomed for its own sake"? One finds rather that very often the oblivion of general anaesthesia is feared as much as, or more than, the operation itself.

2. "... Those whose hands cannot be gentle and whose tongues must wag while they work should be discouraged from surgery under regional anaesthesia." Surely such exponents of what should be an art should be discouraged from its practice altogether. General anaesthesia can be no excuse for clumsiness. And if tongues must wag—as they must when the surgeon is teaching—cotton-wool in the patient's ears solves that difficulty.

3. There is no question of "forcing an unwilling patient to remain awake." Premedication, which plays so great a part in local anaesthesia yet earns no mention in the annotation, prevents psychological disturbance of the patient.

4. Should the patient choose his anaesthetic? Does one ask him if he prefers ether to chloroform? Where regional anaesthesia has proved its safety and efficacy—as in brachial and caudal blocks, intercostal block, infiltration block for herniotomy, dorsal nerve block for circumcision—he will nearly always accept the anaesthetist's advice if the question is raised at all.

5. Though the "constant search for a local anaesthetic drug which, while giving effective anaesthesia, is relatively non-toxic" still goes on and will go on, procaine, which holds the field to-day, is far from unsatisfactory or dangerous. It may, indeed, never be superseded, but regional anaesthesia will continue to progress, with British anaesthetists, one hopes, leading the way.

6. With this final quotation one must be in full agreement: "... It will be to the ultimate benefit of everyone that its study is being taken up by anaesthetists rather than as a minor side-line by surgeons." The anaesthetist must master it and its combinations with general anaesthesia. The surgeon must not displace him, but must be able to give his undivided attention to the operation, while his indispensable ally watches the interests of the patient.—I am, etc.,

Calno.

M. ARNOLD,
Capt., S.A.M.C.

Statistics of Neurotic States

SIR,—Having had some part in encouraging Dr. Collier to proceed with the labour for his article (Oct. 9, p. 461), may be permitted a few comments on Dr. Turner's letter (Oct. 30, p. 556)?

Dr. Collier's basic facts—his assessments of the patients—clearly require testing by another study on similar lines, which, it is to be hoped, may be forthcoming. I am sure that Dr. Collier hoped both for this and for criticism and discussion of his findings and interpretations, but I saw nothing in his article to warrant Dr. Turner's final sentence. There is certainly nothing worse than "figures without facts," but he presented all the necessary figures to enable the reader to draw his own conclusions, and the field is still open for the facts to be tested. He gave a clear exposition of the dimensions of his population at risk and of the method of selection of his sample; were this

not so rare in medical literature Dr. Turner might perhaps have been more able both "to understand and to check" his findings.

It is unfortunate that Dr. Collier did not mention why some of the 2,000 cases selected did not appear in his analysis as "cases of ordinary sickness"; but a reasonable inference from Table I is that he saw some of the 2,000 for other reasons. Surely Dr. Collier's data could not be expected to produce evidence on the duration of psychiatric treatment required for his cases? But the number of cases occurring in one year which might need such treatment is still of interest.

His essential findings were, surely, that in one year among those with unduly prolonged disablement there were 280 cases with, in his opinion, manifest nervous or psychiatric disorder, and that this represented a minimum incidence of 3.8 per 1,000 in the basic population at risk. It would be unfortunate if these major findings were blurred by admittedly valid criticisms of some of his minor deductions when the primary figures were fully and clearly presented.—I am, etc.,

Mill Hill, N.W.7.

RUSSELL FRASER.

SIR,—I regret that my anxiety to compress my paper (Oct. 9, p. 461) and thus to save space caused me to omit to state that some of the 2,000 cases were rejected either because the records were not sufficient to warrant inclusion or because they were seen for reasons not directly connected with "sickness." Most insurance societies have some "special rules," the interpretation of which raises issues that are not strictly medical. I rejected them because I felt that their inclusion would obscure the results. I was trying to study "unduly prolonged sickness." I feel sure that the figures in the tables can be relied on as being generally accurate.

I do not consider that my study "proves" anything whatever. More similar studies would be needed before "conclusions" would be justified. I hope my study showed what kind of information on a matter of great importance might be derived from similar sources. Any general practitioner or any officer in charge of large bodies of sick persons could carry out a similar inquiry. I hope to be able to present a further study in a few years' time if there still seems a useful purpose to be served by carrying it out.—I am, etc.,

Worcester.

HOWARD E. COLLIER.

Mosquitoes in Static Water Tanks

SIR,—This correspondence (Oct. 2, 23, 30) has largely become a discussion about the practical value of larvivorous fish. In Persia all house compounds, even the smallest, and all gardens have "static" tanks, so that, even on the high and very dry plateau, there is plenty of malaria, most of it "man-made." In the grounds of the British Legation at Teheran (extensive and many tanks) we proved that goldfish devoured the larvae, and thereafter we were not troubled except by occasional immigrants. We also provided fish for the summer Legation and the Persian village hard by. They bred fast and their colour made untrained inspection easy. Theoretically their universal use would stamp out malaria in a large city like Teheran. Whether *Carassius auratus* would appreciate the conditions in some of our static tanks is another matter. However, a very experienced observer, your correspondent J. F. Marshall of the Bureau of Mosquito Control, assures us that here it is largely a question of "non-biters" and that oil and larvicides are to be had. Authorities can therefore prepare and act promptly if necessary. Owners of garden tanks would do well, however, to keep goldfish in them. Or does war with Japan mean yet another "world shortage"?—I am, etc.,

Droitwich.

A. R. NELIGAN.

"Descriptive" Medicine in the Lay Press

SIR,—Cannot something be done to prevent the publication in the Press of ill-judged and lurid details of medical therapeutics? Under the guise of helpfulness certain papers present the general public with details of modern medical methods and discoveries. Actually they are merely making "copy" in a quite unjustified journalistic manner for their own ends. In fact they are being "sensational."

In a Sunday paper recently there appeared a description of electrical shock therapy with such sentences as, "A drastic treatment of electric shocks," "A tremendous drama,"

"The result is frightening to watch. The patient loses consciousness and jerks into convulsions like a man in an epileptic fit," and "These dramatic fits." While the purpose of this article was to show that melancholia with suicidal tendencies can now be cured, the effect will be quite the opposite..

Those of us who use this method know only too well that patients are extremely interested in what happens to them during this treatment, and that they are frequently worried lest they should say or do something which will make them appear ridiculous. Other depressives before undertaking treatment inquire anxiously what will happen during the treatments. Well, they now have their answer; it will be increasingly difficult to reassure them or their friends, and very probably many sufferers will now prefer to continue their misery rather than suffer "five or six of these dramatic fits," especially if they have seen a genuine epileptic fit!

Psychiatrists and psychiatric social workers are doing everything to encourage the timid and frightened psychoneurotic and psychotic patients to seek early treatment. This sort of irresponsible journalism is not likely to make their job any easier. It is to be hoped that in future the medical profession will be given some sort of say in matters of health publicity. Perhaps a "medical corporation" will be permitted to exercise some form of censorship in these purely medical matters.—I am, etc.,

T. MARTIN CUTHBERT.

Ryhope, Sunderland.

Fixing Stretcher for Artificial Respiration

SIR.—In the recent correspondence regarding the "Eye" method of artificial respiration suggestions have been asked for a suitable and quick method of fixing the stretcher on a bar. The accompanying photograph shows a one-piece metal

"hood" which can be positioned quickly, and is prevented from sliding by two bolts with butterfly nuts. The clamp was made by Mr. W. Wardrop of this post.—I am, etc.,

J. ALLAN WHITE,

M.O., Ardrossan-Saltcotes First-aid Post.

The Human Side of Medicine.

SIR.—Without in any way questioning Dr. Stark Murray's sincerity (Nov. 6, p. 591), one must wonder how he conceivably arrives at the belief that "the change over from an individualistic system of medicine to a comprehensive national service will give us the opportunity to humanize completely the relationship between patient and doctor. . . ." One indeed questions what humane treatment means to Dr. Murray. Others beside myself no doubt saw State medicine in action in Socialist Vienna—magnificent hospitals magnificently equipped, where the patient was just "Case No. 793," and often treated in a way that would never (up to now) be tolerated anywhere in this country. This was not because the doctors and surgeons of that famous medical centre (in pre-Nazi days) were any less humane than their counterparts in London, but because the relationship between patient and doctor had been brought down to the level of that between the taxpayer and the income-tax inspector—not a person but a thing, not a personality but a body. Does Dr. Murray seriously consider that his relationship to an individual in his "official capacity" is ever more human than to that individual as an individual?—I am, etc.,

London, W.1

ALAN MABERLY.

Obituary

W. BURTON WOOD, M.D., F.R.C.P.

Dr. Wilfrid Burton Wood died on Nov. 2 at Shalford, near Braintree, aged 59. He was the son of a Manchester merchant who had long family associations with that city. Dr. Burton Wood went to the Leys School and later to Jesus College, Cambridge, and to St. Bartholomew's Hospital. He served in the Middle East during the last war, and on returning to England in 1921 started his public health career in the Tilbury Dock area as tuberculosis officer. He very quickly revealed his interest in all manifestations and aspects of tuberculosis, and never spared himself in doing the very best for every patient. The part-time medical officer of health retiring, he was asked to take over the duties of M.O.H., and thus filled one of those pioneer combined medical officer posts which have been carefully fostered in the County of Essex and since adopted throughout the country. He spent most of his spare time at week-ends and holidays in doing voluntary work at the London Chest Hospital, and on taking his M.R.C.P. he was put on the honorary staff of that hospital.

With the wide and valuable experience he had obtained he took up private practice as a consultant physician in London in 1926. He was appointed senior clinical tuberculosis officer to the County Council of Essex. He was particularly interested in the Essex County Council Hospital at Black Notley, where he attended regularly for the treatment of women and children suffering or suspected to be suffering from pulmonary tuberculosis. Later he was to carry out the same work at both the Harold Court Sanatorium and the Essex County Council Hospital, Broomfield Court. Special consultative clinics for Essex tuberculosis officers were conducted by him at the Essex County Council Hospital, Black Notley, and also the London Chest Hospital. He had the knack of attracting to himself disciples who enjoyed nothing better than one of his clinical demonstrations where cases were seen and discussed on the most equal terms.

In 1940 Dr. Burton Wood was elected F.R.C.P. His many writings on the varied aspects of chest diseases, particularly in children and adolescents, and his profound knowledge of radiographic pictures of the lungs, often provoked valuable discussion. He has undoubtedly been the spearhead of the antituberculosis campaign in Essex during the last twenty years, and his passing will leave a gap extremely difficult to fill. His command of the English language was extraordinary; he had the gift of expressing his thoughts in a telling and interesting, and often humorous, manner. As a lecturer he was outstanding, and in every utterance revealed the extent of his reading and studies. He was never afraid to express his opinions, usually in a forthright manner and always to the benefit of those with whom he came in contact. He was a most delightful colleague.

W. A. B.

F. J. POYNTON, M.D., F.R.C.P.

H.L.T. writes: The death of Frederick John Poynton could have caused no surprise to those who had seen him recently. Poynton was a character and sometimes appeared almost wishful to be an oddity. He was a countryman, and deliberately retained a countryman's characteristics with a certain scorn of personal appearance.

Short and stocky in build, he was enormously strong. He held the curious record of captaining a first-class county cricket eleven after attaining to the sober dignity of a Fellow of the College of Physicians. His outstanding cricketing feat was achieved in two hours at Hove when he and Sammy Woods scored 305 runs at top speed for Somerset against Sussex, and he loved to recall the episode. In his cricketing days he was always known as Joseph, and in the pavilion at Lords during big matches he would be affectionately greeted by many old friends. He played hockey for Middlesex and had some skill at real tennis. He had a fine tenor voice and sang for many years in the choir of St. James's Church.

Unfortunately he allowed his professional life to be clouded by what he considered to be the unsympathetic attitude of the profession towards his researches on rheumatic fever, though his resentment never extended to individuals. When speaking in public and at medical meetings he seemed to delight in speaking some illogical standpoint, and while he amused his audience he was not taken very seriously. But when he dealt with a sick child he had a knack of talking spontaneously as if they were equals, and every child felt at ease with him.

He was a delightful personal friend and a great companion on a holiday. He enjoyed every moment, even when missing a critical

short putt and backing his car by mistake on to an outraged goat, which instantly attacked him. Life was not too kind to him and some blows left their mark, but to the end he retained his power of boyish enjoyment, his sincerity and his honesty and his love of children.

Medical Notes in Parliament

"Pay-as-you-earn"

In the House of Commons on Nov. 2 Sir JOHN ANDERSON stated that since the question of "pay-as-you-earn" income tax was debated he had given very careful consideration to the possibility of extending the scheme to the whole range of Schedule E incomes. He had found, not unexpectedly, that a fresh problem emerged and gained importance as they mounted the income scale. That fresh problem arose from the possibility of an adjustment between profits, which were assessed under Schedule D, and income assessed under Schedule E. Such adjustment would be quite lawful in a variety of cases and, if no special safeguard were applied, might result in the loss of considerable revenue. He was advised that the only fully effective safeguard would be to levy a supplementary assessment on any increase of remuneration in respect of the current financial year. He gave an assurance that either in the next Finance Bill or in a special Finance Bill he would include a provision extending "pay-as-you-earn" to the whole range of Schedule E taxpayers, with the appropriate safeguards, which the House could debate. If the House passed the next Finance Bill including these provisions it would make no difference to the date on which the benefit of "pay-as-you-earn" was given to the taxpayers not included in the present Wage-earners Income-tax Bill, because it could be arranged that the charges in the cases (of over £600 a year) not now covered should take effect from the same date—the beginning of the next income-tax year.

Food and Health in India

The food situation in India was debated by the House of Commons on Nov. 4. Mr. AMERY said pressure of population against the means of subsistence was India's gravest problem. Improved health conditions had contributed to it. In the last 12 years the population of India had grown by 60,000,000. Every month over 300,000 additional mouths had to be fed in British India alone. The impact of war had jeopardized the precariously balanced structure, and a year ago widespread, possibly universal, famine had threatened India. That menace was brought within narrow limits. This year Bengal had been affected by local calamities and an all-over shortage. In the last three months every effort had been made to get food through to Bengal. The Bengal Government had taken steps to move all destitutes from Calcutta to relief camps where they could be fed and medically reconditioned. Field ambulances, clearing stations, and medical staffs were being made available for the establishment of a large number of small hospitals. We had released from this country 500 tons of dried milk and South Africa had offered a quantity of milk products.

Sir JOHN ANDERSON reported that the main paddy (rice) harvest in Bengal this winter promised to be very good. If it proved so, they should be near the end of their troubles. At the end of the year the British Government would review the situation again.

Mr. COATES said 1,000 people were dying weekly of starvation in Calcutta and 50,000 in the country districts.

Hospital Domestic Staff: Conditions of Service

In a statement to the House of Commons on Nov. 4 Mr. ERNEST BEVIN said that he had considered the proper organization and supply of domestic staff in wartime to institutions caring for the sick. He found that there was a lack of any recognized rates of pay, etc., and without these effective action on a large scale was extremely difficult. He therefore appointed at the end of July a committee, under the chairmanship of Sir Hector Hetherington, to advise on the rates of pay and other conditions of employment. The report of the committee had been received, and he proposed to accept its recommendations. Where certain conditions were fulfilled he would deal with recruitment to this work in exactly the same way as to any other form of national service, whether in industry or the Services, according to the priority allotted to it and including the use, as necessary, of powers under Defence Regulations. He was appointing a small standing committee to advise on any further steps which should be taken on such matters as training, welfare, etc. He was also concerned with the problem of the private household suffering undue hardship owing to sickness, childbirth, or other emergency. Plans for dealing with such cases were under consideration.

Our Parliamentary correspondent adds that the rates and conditions proposed in the Hetherington report will not be compulsorily imposed on all hospitals and kindred institutions. Domestic staff will only be directed by the Ministry of Labour to hospitals and other institutions which comply with Hetherington report. Existing agreements made with institutions in respect of domestic staff will be accepted as substitutes for the Hetherington scale. The Ministry aims at ensuring that hospital staff meals are as good as factory canteen meals, and will hold the governors of hospitals responsible for ensuring this. Mr. Bevin is willing to develop training cooking for women entering the domestic service of hospitals. The decisions which he announced on Nov. 4 will apply to private nursing homes and private mental hospitals.

Deaths from "Tonsillitis."—Mr. ERNEST BROWN stated on Oct. that tonsillitis was not separately identified in the International List of Causes of Death adopted as the basis of classification in this country, but deaths therefrom were included and constitute the major portion of those under the heads "Septic Sore Throat" or "Other Diseases of the Pharynx and Tonsils" in respect of which specific mention of tonsils or tonsillectomy was made in the death certificate. The numbers of such deaths registered in England and Wales in the four years 1939 to 1942 were 512, 478, 386, and respectively. The information was not available for years before 1939.

A Pensions Grievance.—Mr. QUINTIN HOGG on Oct. 21 raised the case of the widow of Mr. William Brenner Hight, a surgeon employed at the Wingfield Hospital, Oxford. Mr. ARI HENDERSON, in reply, said Mr. Hight was an orthopaedic surgeon of great ability who volunteered for service in a special appointment in South Africa at the request of the War Office. His appointment carried with it the rank of major. Mr. Hight was commissioned with the rank of lieutenant. The Secretary of Central Medical War Committee then informed the War Office that Prof. Seddon, under whom Mr. Hight worked, considered Hight should be given full specialist status with the rank of major. A reply was made on behalf of the D.G.A.M.S. saying that Hight on assuming his overseas appointment would be raised to full specialist status. This would carry the rank of major. Mr. Hight died as the result of enemy action at sea. Under the provisions of the Warrant the award was dependent on the paid rank held at the time of the casualty, and at the time of his death Mr. Hight was being paid as a lieutenant. Mr. Henderson said the War Office was here bound by the provisions of the Pay Warrant. In accordance with the regulations which operated to-day, the pension to be assessed on the pay for the rank he held at the time of death; but in view of the strong representations made in the House Mr. Henderson promised to convey to Sir James G. the feeling of the House that this case should be given special consideration.

Surgical Care of British Prisoners in Germany.—Mr. SORREN on Nov. 2, asked the Secretary of State for War the number of British prisoners of war recently returned from Germany who received surgical attention in Germany as the result of wounds received during the war; how many were fitted with artificial limbs by German authorities; and whether he had received a report regarding the general surgical and medical treatment that our soldiers received. Sir JAMES GRIGG said that detailed information was not yet available but was being collected. Very few of these men were fitted with artificial limbs by the German authorities. Most of them had reasonably effective appliances improvised in camp workshops. In general there were few complaints from the prisoners about medical treatment, much of which was, however, carried out by British medical personnel.

Diphtheria in Immunized and Unimmunized.—Mr. ERNEST BROWN has stated that returns from local authorities in England and Wales for periods between Jan. 1, 1940, and June 30, 1943, showed that among approximately 107,000 children who were notified during those periods as suffering from diphtheria approximately 9,500 in the aggregate had completed the course of immunization. The returns for the year 1942 showed that among approximately 1,530 children known by local authorities to have died from diphtheria in that period 41 had completed the course of immunization. The corresponding provisional figures for the first six months of 1943 were 600 and 21.

Antifreeze for Doctors.—The Regional Transport Commission have been asked to consider favourably applications for antifreeze made by doctors, nurses, and other persons engaged on essential to the war effort, provided that the nature of the work is such that they cannot reasonably be expected to adopt alternative measures against frost—for example, draining their radiators.

Fluorescent Lighting for Daylight.—It is the policy of the Ministry of Works to provide fluorescent lighting in rooms from which daylight is excluded and where important war work is carried on. The Ministry is not aware of any grounds for suggesting that the light is deleterious to the human eye, provided precautions are taken to prevent flicker.

Notes in Brief

Mr. BROWN announced on Nov. 4 that an offer he recently received on behalf of the Government to present to the Soviet Government two of the mass radiography units now being manufactured in this country had been accepted. They would be sent to Russia immediately. One was to go to Stalingrad and the other to Leningrad.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 30. Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

† Includes puerperal fever for England and Wales and Eire.
‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of scarlet fever rose by 306, those of whooping-cough by 234, and of measles by 39; the incidence of diphtheria fell by 23, and of cerebrospinal fever by 20 cases.

The increases in scarlet fever and whooping-cough were due mainly to the experience of the North. In whooping-cough the largest rises were in Lancashire by 62 and in Yorks West Riding by 31. The biggest increase in scarlet fever was in Yorks West Riding (50 cases more), London and the south-western counties reporting a decline. The higher incidence of measles, on the other hand, was due to a rise of 65 in the south-east. In the north there was a tendency for a decline, the biggest drop being in Lancashire (46 cases fewer). The 26 notifications of cerebrospinal fever constituted the lowest total recorded in any week since the rise following the outbreak of war.

Dysentery was as prevalent as ever, only one case fewer than in the preceding week being reported. There were two relatively large outbreaks during the week—in Dorsetshire (Sherborne U.D. 35), and in Bedfordshire (Biggleswade R.D. 29). The other large centres of infection were in London 54, Lancashire 22, Middlesex 15, Surrey 15, Northumberland 13.

In Scotland notifications of diphtheria were down by 67, and of scarlet fever by 33, while the incidence of acute primary pneumonia was up by 63 cases, of whooping-cough by 51, of measles by 27, and of dysentery by 21. The increase in the notifications rose from 5 to 29. The western area was responsible for the drop in scarlet fever and for the increase in measles. The rise in pneumonia and the fall in diphtheria were fairly general throughout the country. The chief alteration in local trends of whooping-cough was an increase in Glasgow from 85 to 115.

In Eire the chief feature of the returns was a fall in diphtheria from 187 to 101.

The Week Ending November 6

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 3,374, whooping-cough 1,755, diphtheria 770, measles 553, acute pneumonia 676, cerebrospinal fever 44, dysentery 146, paratyphoid 4, typhoid 4.

The Health of the Nation

The nation's health at the beginning of the fifth war winter was reviewed by Sir Wilson Jameson, Chief Medical Officer of the Ministry of Health, at a Press conference on Nov. 5. Deaths from respiratory tuberculosis, which rose sharply during the first two years of war, have declined. The number of deaths—5,297 during the June quarter of this year—is below the number (5,540) of the corresponding quarter of 1939. Deaths from tuberculous meningitis are above the 1939 level, but other forms of tuberculosis are now in the same position as in 1939. There were fewer deaths from all forms of tuberculosis during the second quarter of 1943 than in the same period of 1939. While this is a gratifying position, Sir Wilson gave a warning that an increase may occur in the future, as there was a 3% increase in cases last year.

The epidemic of cerebrospinal fever which broke out during the early months of the war has been gradually subsiding, and this disease now approximates to the pre-war level. During the June quarter of this year there were 198 deaths, compared with 152 in the second quarter of 1939.

Notifications of some infectious diseases have risen, and the June quarter of this year there were 198 deaths, compared with 152 in the second quarter of 1939. The slight increase is with scarlet fever, and whooping-cough are more prevalent than at the same time last year. The slight increase is with measles, scarlet fever, and whooping-cough are more prevalent than at the same time last year. The slight increase is with measles, scarlet fever, and whooping-cough are more prevalent than at the same time last year.

The low prevalence of enteric fever was "really astonishing." The decline in the cases of and deaths from diphtheria continued, and during the first half of this year 650,000 children were immunized, an average of 25,000 a week. During the eighteen months Jan., 1942, to June, 1943, and in only 62 of these had the children been immunized. The total number of deaths from diphtheria during the June quarter was the lowest ever recorded in any year.

Discussing the infant mortality, Sir Wilson said that more intensive study of this problem was required. Although the figure was declining and the rate of the September quarter was expected to be the lowest ever recorded for a third quarter, the rate for Britain compared unfavourably with some other countries. In many of the large cities of the United States the infant mortality was well below 40, and if this could be done in America it could be done here when conditions made a new campaign possible.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

N. Whittaker, M.B., B.Chir., has been approved for the degree of M.D. in absence. The degrees of M.B., B.Chir. were conferred by proxy upon J. W. Fawcett at a Congregation held on Oct. 30.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The Duke of Gloucester has honoured the College by accepting its Honorary Fellowship. This forms a fitting climax to the celebration of the centenary of the F.R.C.S. and is particularly pleasing because it enables the Council to show appreciation of His Royal Highness's work for the sick and wounded in his capacity as President of the War Organization of the British Red Cross and Order of St. John, King Edward's Hospital Fund for London, and the British Empire Cancer Campaign.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the quarterly meeting of the College held on Nov. 2, with the President, Dr. Charles McNeil, in the chair, Dr. Ian Murray (Glasgow) and Dr. Harry Stalker (Edinburgh) were introduced and took their seats as Fellows of the College.

The Hill Pattison-Struthers Bursaries in Anatomy and Physiology, and Clinical Medicine, were awarded to William Rhind Brown and Peter Douglas Kemp, respectively.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

By order of the Council, Regulation 3 for the D.R.C.O.G., relating to practitioners who have not fulfilled the requirements of Regulation 2 in respect of resident appointments, will be suspended after March 1, 1944, for the duration of the present emergency.

Medical News

The address of the National Smoke Abatement Society is now: Chandos House, Buckingham Gate, Westminster, S.W.1.

The British Institute of Philosophy announces a lecture entitled "Our Knowledge of Other Minds," to be given by Mr. D. M. Mackinnon at University Hall, 14, Gordon Square, W.C., on Friday, Nov. 26, at 3 p.m.

A conference on the causes and prevention of pre-natal and neonatal deaths will be held on Thursday, Nov. 25, at 4.30 p.m. in the Council Chamber, Paddington Town Hall, with Dr. G. de Swiet in the chair.

At its next sessional meeting in Chesterfield Town Hall on Nov. 27, at 10.30 a.m., the Royal Sanitary Institute will hold a discussion on houses of the future, with special reference to the housewife's needs. The honorary local secretary is Dr. J. A. Stirling.

A refresher course in tuberculosis for general practitioners will be held on Thursday afternoon, Dec. 16, and all day Sunday, Dec. 19, at the Medical Society of London, 11, Chandos Street, W.1. The course has been arranged by the Joint Tuberculosis Council and National Association for the Prevention of Tuberculosis Joint Committee on Education, in collaboration with the Local Medical and Panel Committee for the County of London and the London Public Medical Service. The fee is £1 11s. 6d. An applicant who is a member of the London Public Medical Service may have the fee remitted by that body and deducted from his account. Early application should be made to Dr. Harley Williams, Tavistock House North, W.C.1. Lecturers and subjects are as follows: Dr. Joseph Smart, "Modern Methods of Diagnosis"; Dr. James Maxwell, "Some Points in Home Management"; Mr. T. Holmes Sellors, "Collapse Therapy"; Dr. Peter Kerley, "Diagnosis by X Rays"; Dr. C. H. C. Toussaint, "Facilities offered by Local Authorities for the Prevention, Diagnosis, and Treatment of Tuberculosis"; Dr. W. P. H. Sheldon, "Tuberculosis in Children"; Dr. Andrew Morland, "The Peculiarities of Tuberculosis."

The Government of India has appointed a committee, with Sir Joseph Bore as chairman, to investigate all aspects of public health in India, both curative and preventive. The committee is part of the Government plan for post-war reconstruction. It will first survey the whole field, including health and medical relief services, health education and propaganda, nutrition, industrial conditions in relation to health, and nursing services, and will afterwards suggest a plan for development. Subcommittees have been set up to deal with public health, medical relief, industrial health, medical education, and medical research.

Surg. Cmdr. George A. Mason, F.R.C.S., has been appointed thoracic surgeon to the British Legion Village (Preston Hall, Maidstone, Noyland Sanatorium, near Colchester, and Devon House, Bournemouth). His appointment began on Nov. 1. Since the death on service of Mr. Laurence O'Shaughnessy in the 45 days of the war, there has been an interruption in major thoracic surgery at Preston Hall, but it is now hoped to utilize Preston Hall as a centre for surgical treatment of patients from all three institutions now under the British Legion.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on reprints. Authors over-seas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Atiology*, Westcent, London; SE

TARY, *Medisecra* Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pernicious Anaemia and having Children

Q.—An apparently healthy woman of 30 has relatives who are from pernicious anaemia. (1) Her mother has had it for many years and is under constant liver therapy; she has a proved achlorhydria. (2) Two of her mother's brothers have died from this disease; a third suffers at present. (3) Her sister at the age of 29 had subtotal hysterectomy for fibroids and very nearly died after operation from haemorrhage of haemophilic type; she was only by numerous blood transfusions; she was later found to have a colour index over 1 and an achlorhydria. The woman refuses to undergo blood or gastric juice investigation, but insists that it will be quite safe for her to have a child. Should this woman be allowed to have a child from the point of view of (a) her own safety at parturition and (b) the child inheriting a tendency to a haemopoietic disorder?

A.—The woman's refusal to undergo investigation of the blood and gastric juice is probably based on the fear that pregnancy will be forbidden if an abnormality is found. In this connexion it should be remembered that precipitation of pernicious anaemia in disposed subjects during pregnancy is rare, and that not a few patients with known pernicious anaemia have now been safely through pregnancy. As regards the argument that the child inherits a tendency to haemopoietic disorder, surely the choice must be left to the woman. It is no more than even chances that she herself has a tendency to pernicious anaemia. Even if she has more than half her children are likely to inherit this tendency, not all with the tendency will develop the disease. Since pernicious anaemia rarely develops until late in life; and can be completely controlled by treatment, the argument for forbidding conception because of the risk of transmission of suffering is not very strong. The woman should therefore be permitted to have a child if she desires one strongly, but in return she should agree to the examination of her blood monthly during the first seven months, and nightly during the last two months of pregnancy. The blood should also be grouped. With these precautions there should be no interference with the development of an uncontrollable state of anaemia.

What is a Yawn?

Q.—What is the function, or purpose, in Nature, served by yawning? Information as to the physical mechanism effecting the phenomenon would also be welcomed.

A.—Considering the frequency of occurrence of yawning in the human subject, it is surprising to find so little reference to it in the literature. None of the standard textbooks makes any reference to it, and there does not appear to be any experimental work on the physiology of its causation. Yawning consists of a full inspiration, with wide-open mouth, which is held for a second or two and followed by a fairly rapid expiration. It is usually accompanied by extension—"stretching"—of the limbs and trunk. It usually seems to occur when a mild degree of cerebral anoxia is likely and when the respiratory centre may be depressed—e.g., after sitting for some time in a warm, close, sphere, on waking, or under conditions leading to boredom or relaxation of attention. In these cases it seems likely that there is some reduction of cerebral blood flow, and a consequent anoxia. Yawning is also reported in individuals resting at high altitudes.

d in some forms of epidemic encephalitis. There does not appear to be any record of its occurrence as a result of muscular fatigue associated with mental fatigue, or in any conditions where a full rebral flow of well-oxygenated blood is assured. In the infant it is an early form of response and has been reported as occurring within five minutes of birth.

Breathing is controlled through a central respiratory mechanism which, according to Lumsden, consists of pneumotaxic, apneustic, and gasping centres, or, more recently, according to Ranson and his workers, of inspiratory and expiratory centres. The activity of pneumotaxic and apneustic centres, or inspiratory and expiratory centres, is co-ordinated through reflexes. Interference with these reflexes affects the pattern of breathing. Although there is little experimental evidence to warrant it, a comparison may be made between yawning and the apneustic type of respiration which occurs in the upper part of the pontine portion of the respiratory regulating centre is interfered with; apart from section of the brain stem, anoxia induced by a variety of methods may induce apneustic breathing, and it is assumed in these cases that the depression of the centre by anoxia occurs from above downwards. Yawning might be regarded as due to unopposed action of the apneustic or inspiratory centre owing to anoxic depression of the pneumotaxic centre—the co-ordinating reflexes. The increased oxygenation of the blood and its more rapid circulation, caused by the deep inspiration of yawning and the associated muscular movements, will lead, at least temporarily, to the disappearance of the depression. Some observers, however, regard yawning as a form of emotional behaviour, particularly in animals. Charles Darwin in *Expression of emotion in Man and Animals* refers to yawning in baboons and one of the smaller monkeys as a sign of apprehension or anger; and, in dogs, yawning, apart from occurring in similar circumstances to those causing it in man, is often seen when the animal is apparently puzzled. It is difficult to see any connexion between these types of yawning and that which may be caused by anoxia, or does the anoxic theory explain the "infectious" yawning which may be induced in a group of people by one individual acting as a stimulator. There is some experimental evidence that this group response can be induced independently of the environment, though it is usually influenced by it.

Chlorine and Phosgene Gas Poisoning

Q.—What immediate steps should be taken in the management of chlorine and phosgene gas casualties before they are admitted to hospital? Is it, for example, necessary for them to pass through a decontaminating station? If the hospital to which they are sent has facilities for treatment but no decontaminating station attached, what is the proper course to pursue?

A.—Casualties poisoned by phosgene gas, or, rather, lung-irritant gases, or suspected of being so poisoned, should be warmly wrapped in blankets, placed on a stretcher, labelled with the symbol XX on plain luggage label, and sent as soon as possible in an ambulance on the incident direct to a hospital. Where the incident occurs at a distance from a hospital, and there is no ambulance immediately available to convey the casualties there, they should be conveyed on stretchers to a first-aid post or other suitable place under cover, where they can be kept quiet and warm and under proper supervision till they can be taken to hospital. Warmth and complete physical rest in the fully recumbent position are essential for these cases whilst they await transfer to a hospital, as the danger to be feared is the onset of pulmonary oedema. Hot sweet tea may be given at this stage.

Chlorine and phosgene gases are both non-persistent gases. No decontamination of the clothing and no cleansing of the person is therefore necessary. Indeed, any attempt to cleanse such persons will tend to accelerate the onset of the pulmonary oedema and so must be avoided. Persons exposed to the non-persistent gases are not contaminated, their clothing does not require removal, they must not be labelled with the symbol C, and they can be transported in an ambulance without contaminating it or the blankets in which they are wrapped.

The questioner would do well to read the two books, A.R.P. Handbook No. 2, 4th edition, May, 1943—*First Aid and Nursing of Gas Casualties*, price 4d.; and *The Medical Manual of Chemical Warfare*, Feb. 28, 1943, price 2s. 6d. net.

Incomplete Erection

Q.—A patient of 30, after psychotherapy for semi-impotence and diminished desire, has now almost recovered his previous full powers. Before the psychotherapy a neurologist had excluded organic disease. However, complete erection is confined to the corpora cavernosa penis. That in the corpus cavernosum urethrae and glans penis remains partial. Is this likely to be an organic or a psychogenic disability—and would any further treatment be of use?

A.—An incomplete erection of this kind is almost certainly psychogenic in origin. The fact that it has been so accurately described by the patient to his doctor suggests that the patient is

still preoccupied with the state of his organ during intercourse. Instead of his attention being on his wife and his mind filled with sexual excitement, he is noting the exact state of his penis, wondering whether it will get more rigid, anxious lest the erection should subside, etc. In other words, the higher centres in the brain are interfering with, instead of stimulating, the erection centre in the cord. If a man is preoccupied with the state of his stomach and with the sensations coming from it after a meal he will eventually bring about a disturbance of its natural activity. In the same way the mind can easily derange the equally mechanical activity of erection.

Spasmodic Torticollis

Q.—Can you help me with a case of acute torticollis in a woman of 34? This began with spasm of the right sternomastoid about three months ago. It was then painless. She has had encouragement and phenobarbitone, which did no good at all. She is now in bed; and when she is lying down the spasm, which is now painful, entirely disappears. Massage makes her worse. The spasm recurs as soon as she raises her head from the pillow. She has seen a psychologist, who did not think the condition was psychological.

A.—If a psychiatrist has excluded a hysterical cause for spasmodic torticollis with certainty, the outlook is unfavourable. More often than not the disorder has a physical basis, and indeed structural changes in the basal nuclei have been described. The story of a gradual onset and relief by lying down or by sleep is typical. Treatment is very difficult. Some patients can inhibit the involuntary movements by holding the chin lightly, but springs which have been advised for the same purpose are usually unsuccessful. Surgical treatment—section of the spinal accessory nerve, the motor roots of the upper cervical nerves on that side, or of the motor and sensory nerves—may give great relief. This is usually temporary, since, as the condition is due to a central disorder, other muscles take up the movement. Large doses of sedatives should be tried, but antispasmodics such as stramonium and atropine are disappointing. When torticollis is not hysterical in origin it is liable to persist.

Ascites in Case of Malignant Ovary

Q.—In a case of ascites due to malignant disease of the ovary it is impossible to remove much fluid because of clotting in the cannula or tubing. How can this be avoided? Would injection of 30% sodium citrate into the peritoneal cavity be of any help?

A.—The premise seems to be faulty. Ascitic fluid due to malignant disease of the ovary is usually thin and easily removed by tapping; rapid clotting is not a special feature. The cannula used may have been too small; or, more likely, it has penetrated a walled-off portion of the abdominal cavity. If the fluid is thick and jelly-like, pseudomyxoma peritonei should be suspected; in these cases it is necessary to open the abdomen in order to evacuate the tenacious secretion. If the diagnosis has not already been clinched by exploratory laparotomy, this should still be done. Injection of sodium citrate is not likely to be helpful because, even if it influenced clotting, it would be difficult to get it to mix intimately with the large quantity of intra-abdominal fluid presumably present.

Neurofibromatosis

Q.—A patient aged 50 suffers from a multiple neurofibromatosis. He has the swelling over the whole body and new ones are continually growing. As they grow they are very painful. Is there anything I can do to check or cure this distressing complaint? He has tried thyroid medication but without any real effect. (I might mention that he suffers from occasional allergic reactions to certain foods.)

A.—In generalized neurofibromatosis of this sort I do not think any specific treatment of avail. Large, painful fatty swellings or small superficial fibromata can be excised, but the condition is a neoplastic one, quite unlikely to respond to endocrine or dietary treatment. Death is often caused by the onset of malignant changes in some of the tumours; or by intracranial pressure caused by a fibroma in the acoustic nerve.

Sulphonamides for Dysentery and Colitis

Q.—Have the sulphonamides, or a variant, been used in the treatment of colitis and dysentery? A nephew of mine has been troubled, ever since his service in H.M. Forces during the last war, with colitis. To my knowledge he has not had an examination of the faeces to establish the presence or absence of a Shiga or Flexner bacillus (he has not been under any professional care). His health has been undermined by these attacks, in spite of which he insists upon taking an active part in Civil Defence. I have a vague recollection of having read in the "B.M.J." of sulphonamide medication being tried in his complaint. I should be grateful for some information on this point.

A.—Several of the many recent papers testifying to the value of sulphaquinoxaline in the treatment of acute bacillary dysentery appeared in this *Journal*. Sulphaquinoxaline is a drug of low solubility, the greater part of which is consequently retained in the bowel and acts there; other sulphonamide compounds are

completely absorbed long before the colon is reached, and therefore act only in the tissues and not in the lumen of the bowel. Succinylsulphathiazole ("sulphasuxidine") is a newer compound of the same type; even less of it is absorbed, and it may prove to be superior for intestinal treatment even to sulphaguanidine. There is less information about the treatment of ulcerative colitis, with varying results, possibly because the disease so named has various causes. In this case there should be at least a simple naked-eye and microscopical examination of the faeces to decide what type of colitis exists, and possibly a sigmoidoscopy. If there is reason to regard it as infective (pus in the stools; ulcers demonstrated), a course of sulphaguanidine might be tried—say 2 g. four times a day for a week. Larger doses of succinylsulphathiazole can be given with no danger of any toxic effects.

Sterilizing Blades and Needles

Q.—What are the best methods of sterilizing scalpel blades and suture needles for operations?

A.—The only simple rapid and certain way of sterilizing any surgical instrument is to boil it for 5 minutes in water containing 2% sodium carbonate. This proceeding, unlike boiling in plain water, can be depended on to kill all bacteria, including spores. The widespread belief that either boiling or dry heat (150° C. for 1 hour in a hot-air oven—also fully efficient) reduces the sharpness of cutting instruments has been contested; if such a change occurs its degree is slight. Sterilization by chemical means is best achieved by solutions containing formalin: Borax 1.5 g., formalin 2.5 c.cm., phenol 0.4 c.cm. aq. dest. ad 100 c.cm. The following has also been recommended recently: Borax 0.1 g.; ac. boric 1.5 g., *p*-chlor-m-cresol 0.2 g., spirit 5.0 c.cm., aq. dest. ad 100 c.cm. (The borax in these solutions prevents rusting.) Spirit, though extensively used with impunity, is an unreliable sterilizing agent. It is totally without action on spores, and may even not kill pyogenic cocci if they are protected by a layer of albuminous material, as may happen on an imperfectly cleaned instrument. For maximum effect it also requires dilution to 70% strength, in which steel instruments rust.

Phosphorus Burns

Q.—In some of the London sections of the N.F.S. a 2% solution of sulphate of copper was issued for application to phosphorus burns, which was to be applied after an initial application of an alkaline solution. Is there a good reason for the withdrawal of the copper sulphate solution?

A.—Burning phosphorus produces acids, and the penetration of these into the tissues aggravates the burn and delays healing. The object of an alkaline solution as an initial application is to neutralize such acids as quickly as possible. The object of the copper sulphate solution is to cover any adherent phosphorus with a dark and easily visible coat (probably a mixture of copper phosphide and metallic copper) so that re-ignition of the phosphorus is inhibited and an opportunity is given for the visual location of any fragments of phosphorus still adherent and their removal. So long as there is reason to suspect the presence of elemental phosphorus the application of copper sulphate remains a necessary procedure.

Moulds on Leather Cases

Q.—I have a number of leather cases—e.g., midwifery, emergency, dressings, diagnostic, etc. These were stored in a cupboard in my surgery, and after a few weeks became coated with mould. Since then I have found it difficult to keep them free from mould. I would be very glad to hear of any suggestions.

A.—Moulds are present in the air almost everywhere, ready to inoculate substances like leather the moment they become wet. An application of thymol dissolved in spirit in the proportion of 4 to 6 g. per litre is used by the leather trade to free and preserve leather from mould.

Post-herpetic Neuralgia

Q.—A patient had facial herpe three years ago. Since then there has been continuous pain in the affected side of the head, made worse by cold and windy weather. I remember reading somewhere that galvanism is of use in such cases. Can you give details of this, or any other form of treatment which might lead to a cure? I am told that various analgesic drugs have been tried without success.

A.—Treatments of post-herpetic neuralgia are legion. Physical measures include local infra-red and ultra-violet irradiation, often combined with general ultra-violet irradiation, galvanism, diathermy, and short-wave therapy. Details of application will be found in any textbook of physiotherapy. X-ray treatment has been recommended by some authors and condemned by others. Local treatment includes light cauterization with the Paquelin cautery and infiltration of the affected areas with procaine solutions. Injections of alcohol into the affected nerves or ganglia and section of nerve roots or tracts have proved of little value. General measures, such

as autohaemotherapy and injections of pituitary extract or vitamin B, have had cures in some hands and failure in others. Success has recently been claimed from the intramuscular injection of cobra venom in a dosage of 5 mouse units (1 c.cm.) daily.

Iritis

Q.—An attack of iritis in 1936 left me with two pairs of synechiae and a small corneal opacity. Otherwise the eye recovers except that it became easily strained and painful after a few hours' reading. All investigations have been made, and nothing abnormal found except septic tonsils, which have been removed. Now, in 1943, I have had another flare-up of iritis for no apparent reason. Are the synechiae in any way responsible for the recurrence? so, is it advisable to have them broken down by subconjunctival injection of mydraine; or, alternatively, what else is suggested to avoid any further recurrence? As every attack of iritis is liable to leave a little corneal opacity, what is suggested as the best treatment for a quick and certain resolution?

A.—There is no valid reason for assuming that synechiae themselves a cause of iritis. That belief prompted the now obsolete operations for surgical division of synechiae. The use of a conjunctival mydraine (atropine, adrenaline, and cocaine compound) would be harmless, but is unlikely to prevent relapses, which some tangible cause must surely be present. Knowledge of the aetiology of recurrent iritis is unfortunately rather sketchy. For the corneal opacities, these represent either an associated corneal reaction or deposits of precipitates at the back of the cornea ("K.P."), and there is no treatment for these apart from the treatment of the underlying condition.

Speculation

Q.—How electroshock therapy produces the results it does produce is still a matter of controversy. An attractive hypothesis is that there is a stimulation of the pituitary gland, which then further stimulates the endocrine orchestra. If this were so, convulsive even subconvulsive therapy should restore a case of myxoedema to normality. I should be interested to know if electroshock has been used for such cases, and to what end. Not only would such knowledge be an addition to the electroshock therapist's armamentarium, but it would also be a pointer as to whether the action is on brain cells *per se*, or on the pituitary gland.

A.—A hypothesis should be based on observed facts. To the best of my knowledge there are no observed facts to support the suggestion made in this question. A general stimulation of the pituitary would be expected to produce an increase in (1) gonadotrophic function, resulting in ovarian or testicular overactivity; (2) thyrotrophic function, resulting in thyroid overactivity; (3) adrenotrophic function, resulting in adrenal cortical overactivity (electrolyte changes, oedema and possibly a condition resembling Cushing's syndrome); (4) growth-producing gigantism in the young and acromegaly in adults; (5) diabetogenic function, producing diabetes or at any rate carbohydrate intolerance; (6) less well-defined effects on gastric secretion and blood formation; (7) high blood pressure, hyperchromic anaemia, achlorhydria, diabetes, and oliguria (the posterior pituitary syndrome of Idris Jones). None of these effects is, in fact, observed.

LETTERS, NOTES, ETC.

Epidermolysis Bullosa

Dr. HUGH S. STANNUS (London, W.1) writes: In your issue of Nov. 6 (p. 597) there is a question re epidermolysis bullosa. In answer no mention is made of the paper by Schwartzman, J., et al (*Amer. J. Dis. Child.*, 1941, 62, 352) on Ritter's disease, and treatment which appeared to be followed by satisfactory response. My child was 1 month old. The treatment was 2 mg. riboflavin 4 times daily, cod-liver oil, and a syrup containing the vitamin complex.

Shortened Puerperium

Dr. G. F. BARNHAM (Gorran, Cornwall) writes: May I add my personal experience of shortened puerperium. My wife had her confinement in 1920 at the Maternité Clinic, Lausanne (3 previous confinements in England with the usual 2-3 weeks lying in). She allowed up on the 3rd day, left the clinic about the 6th day, I recall that we went to the theatre on the 14th day and returned to England, with 4 children, on the 21st day. We have never had reason to regret this. My purpose in quoting this experience is to draw attention to the fact that at this admirable clinic this procedure was, 23 years ago, the normal practice in uncomplicated cases and to put in a plea that, in consideration of the enormous economic advantage of the shortened puerperium, both to the patient and to maternity accommodation, inquiry might be made at Lausanne and other similar foreign institutions as to whether their experience and statistical results have caused them to modify their practice.

THREE SKIN DISEASES IN WARTIME*

BY

HENRY MacCORMAC, C.B.E., M.D., F.R.C.P.

Physician for Diseases of the Skin, Middlesex Hospital

Dermatologists are supposed to be fortunate because they are not called out of bed at night, and because their patients never get well and never die. I have deliberately prefaced my observations with this cynicism since it embodies the germ of a widespread belief in the chronicity and rebellious nature of skin diseases—a belief I desire at once to challenge and to traverse by saying, first, that the majority of skin diseases are characterized by their satisfactory response to treatment provided the established therapeutic principles are followed; and, secondly, that although patients rarely die, the disability—for example, from eczema—has a formidable economic significance: the afflicted individual cannot work, and becomes a liability rather than an asset to the community, and this is particularly true of industrial dermatitis under the present condition of intensive endeavour. In the last war, as Prof. McNee pointed out, 90% of all the sickness in one army resulted from the effects of skin diseases, especially scabies and pediculosis. History repeats itself. It is therefore an important part of our national service to set up a programme with the object of preventing or limiting, so far as we can, a similar wastage of man-power in civil as well as in military life.

I can here only profitably review a very limited cross-section of a large subject, but this will represent the hard core, leaving out the less important, perhaps even ornamental, framework. I have ventured to choose scabies, impetigo, and eczema as a representative group. Scabies and impetigo, as I fully realize, have recently been very widely discussed. The present occasion may nevertheless, and for that reason, be a suitable one to sum up.

Scabies

Note that in scabies the incubation period may be as long as two months; this explains the apparent freedom of the sleeping partner even six or seven weeks after intimate contact. The eruption on the anterior axillary folds and the abdomen consists of scratched papules; on the fingers and wrists occasional vesicles with the characteristic burrow, from which, with practice, the mite can be extracted. In the adult male, papules and impetiginous lesions on the penis provide invaluable confirmatory signs—the means of settling at once the diagnosis in many doubtful cases. The presence of grouped impetigo on the lower buttocks is equally reliable as positive evidence of scabies, especially where the characteristic scabietic eruption is insufficiently or irregularly developed elsewhere. The diagnosis of scabies may be very easy or very difficult. Recognition of its prevalence with a sharp look-out for its presence, even in the most unexpected quarters, will best serve as a means of detection. The deceptive qualities of the disease were well illustrated recently in an in-patient who had typical and almost universal eczema. The routine examination revealed one

burrow on the web between the fingers, from which a living acarus was removed. Here treatment had of necessity to be tempered to the superimposed eczema: this case is mentioned not for this reason, but because it illustrates the importance of a detailed examination even where the diagnosis appears established beyond doubt upon a more superficial survey.

Treatment.—The treatment of scabies as a war measure has been standardized as follows: A hot bath, with soaping, is followed by the application of 25% benzyl benzoate emulsion all over below the neck; the benzyl benzoate is applied again—that is, two applications in all—either on the next day or one week later. To obtain uniformly good results it is important to follow this procedure and this method exactly, no more and no less, and to use the agreed concentration of benzyl benzoate, thus avoiding the pitfalls of over-treatment or under-treatment by one of the many alternative procedures, which, except sulphur ointment, have proved under careful testing to be incompetent in varying degrees. On the question of disinfection of contact garments and bedding I shall find myself at variance with the view that this is unnecessary. Reinfection, I submit, may occur either from other persons in the household, especially the sleeping partner, or from garments and bedding: any complete scheme should therefore exclude reinfection from both these sources, and in this belief I am fortified by, as it seems to me, the minor epidemic occurring among fire-watching parties through communal blankets.

Impetigo

As in the case of scabies, war conditions have revived in epidemic form another parasitic disease—impetigo contagiosa. I am confident that the clinical manifestations of this complaint have become considerably modified during the last two or three decades, the eruption having changed from the delicate circinate blisters and very superficial crusted patches to a much more polymorphic and refractory reaction. Earlier observations seemed to establish a streptococcal invasion of the skin as the causal agency, but it has recently been shown that a staphylococcus may also, and equally, be the causal organism, and there are even some who profess to be able to recognize differences in the clinical picture resulting from each type of infection. Be that as it may, it is at least possible that this alternative parasitology accounts for the greater variation in the clinical appearance. For some curious reason this seems to apply only to impetigo of the facial region. The secondary impetigo of the body and limbs, such as that met with in association with scabies, still breeds true to form.

Treatment.—If impetigo has thus become complicated, its treatment has undergone a remarkable simplification since the introduction and use of sulphathiazole gr. 25 in zinc paste 1 oz.: by some a water-miscible cream as a vehicle is considered superior. The remedy should not be applied for more than six days—first, because by then it has either proved or disproved its suitability; and, secondly, because by prolonged use or inadequate dosage a drug-resistant species of the micro-organism may be created. The alternative treatment relies on ammoniated mercury gr. 10 in zinc paste 1 oz., which should

* A-British Medical Association Lecture given to the Exeter Division at the Royal Devon and Exeter Hospital.

in any case be prescribed for impetigo on the body and limbs. Where the impetigo develops on the face in rings or circles with a superficial raw surface or "stuck-on" crust, diagnosis is easy and straightforward. An infected or impetiginized seborrhoeic eczema also attacks the face, and it is then very difficult to distinguish it from the variety of impetigo with multiple small lesions. An infected eczema is much more symmetrical, the eyebrows may be simultaneously involved, and as a rule the eruption tends to be confluent, in contrast to the areas of healthy skin between the infected regions which are observed in impetigo. When in doubt treatment by dabbing the face with 1 in 2,000 perchloride of mercury lotion, followed by oily calamine lotion, is usually an efficient compromise.

Eczema

For my third and last subject I have chosen eczema because it is always with us, because it has become increasingly prevalent during the war, and because it provides a major problem in the recognition and treatment of industrial dermatitis. Thrice armed indeed is he who is, familiar with the diagnosis, prognosis, and treatment of this, the commonest and most troublesome skin disorder. I have deliberately used the word "disorder" instead of "disease," as this glosses over the differences of opinion of those who on the one hand regard eczema as a specific entity and on the other as a cutaneous reaction provoked by a variety of different internal and external agents. In eczema the minute changes in the skin determine the objective phenomena and also show us how the different clinical varieties are connected. The earliest changes occur in the dermis in the form of dilatation of the papillary and subpapillary blood vessels with exudation of serum. This results in a congestive erythema seen as redness of the skin, most pronounced in eczema rubrum. The serous exudation accounts for the swelling observed in certain acute types of the disease, especially the form affecting the face and genitals. The exudate has further and important effects; for the fluid invades the epidermis separating the prickle cells, and at a certain point the pressure of this fluid ruptures the intercellular filaments, producing tiny cavities filled with serum, constituting the vesicles—the most important and characteristic element of the multiform eruption. If the discharge of serum is considerable a weeping surface is observed; or the coagulated serum may form crusts; or secondary infection may occur; or where an imperfect attempt is made to reproduce the horny surface, squamæ or scales develop. All these changes occur in every case of eczema, but in different degrees, thus constituting the different clinical varieties. To attempt to explain these complicated dermo-epidermic reactions would require a chapter in humoral and cellular pathology far beyond the scope of this address and my own competence. We are, however, entitled to assume as a working hypothesis that in every eczematous eruption both an endogenous and an exogenous factor exist, but in such disproportionate degrees as to require us to classify some cases as examples of endogenous and others as examples of exogenous dermatitis. Or, in the descriptive terms of the patient, either the blood or the skin is at fault, or both. This hypothesis does not require confirmation by laboratory methods; observation of the patient and his reactions provides all the evidence necessary for proof. This leads me to suggest that the modern tendency relies too much on the guinea-pig and the test-tube and too little on that rich and still unworked field of clinical observation.

The first clinical assumption relates eczema to certain age periods. The age incidence of 648 male and 489 female patients taken from my case-books shows a special liability in infancy and early childhood, then a fall, followed by a pronounced increase in the liability to eczema as age advances, reaching a peak at 50 to 60 years. The assumption is that there is an endogenous or constitutional factor in eczema which in certain predisposed people and at certain predisposing ages induces an eczematous eruption. In endeavouring to explain this internal or constitutional factor we are bound to touch upon the theory of a hypothetical allergic mechanism. There is a well-known but rare form of so-called eczema affecting the flexures, developing in early life and persisting for years, which is classified as allergic because of an association with asthma or hay-fever. But an allergic background such as this is very rarely observed in common eczema. Clinical

experience thus entitles us to do no more than concede the existence of a hypothetical internal factor without further qualification. This does not prevent us from recognizing occasional contributory factor, such as focal infection or allergy. Lawyers have a maxim that hard cases make bad law. Those clinical curiosities in which eczema clears after the extraction of a decayed tooth, or the parallel example of the appearance and disappearance of an eruption following the taking or withholding of an article of food, impress, although they may be, are, like the hard cases of the law, very insecure foundations upon which to base practice. The theoretical considerations lead to the following conclusion: Where re-education of the skin is called for in endogenous eczema we are compelled, because of our ignorance of nature of the endogenous factor, to rely on a form of desensitization based upon a non-specific model, such as whole blood injections, peptone, or methods which aim at exciting a febrile reaction. These procedures are based upon constructive clinical observations—for example, the obliteration of eczema during the febrile period of pneumonia: their scientific explanation is still outside the range of pathological or chemical attainment. They hint at the existence of a mechanism for rehabilitation, the shadow factories of Nature, which operate only under conditions of duress.

Some Methods of Desensitization

In 1925 in a communication to the *British Medical Journal* I described the mode and application of some of these relatively unknown methods of desensitization. A ripe experience has confirmed my belief in their value, and I desire to reassert their importance when used under suitable conditions, which I shall summarize as follows.

In the acute phases of eczema, especially those associated with heat and swelling, intravenous injections of thiosulphate of sodium are especially valuable. Five c.c.m. of a 10% solution—that is, a gramme of the pure salt—constitutes a dose; this intravenous injection should be repeated every other day on from 3 to 6 occasions. Whole-blood injections have a wider range of usefulness and may be required in the subacute and chronic stages of eczema. The withdrawal from a vein and the intramuscular reinjection of 5 c.c.m. of the patient's blood every 5 to 7 days for a course of 10 injections provides a suitable routine procedure which can be modified where circumstances seem so to dictate. Intramuscular injections of peptone offer an additional therapeutic resource in rebellious and refractory eruptions.

Procedures such as the above are described as safe, inasmuch as they rarely upset the patient or aggravate the disease. They can therefore be employed freely and with confidence. Methods which seek to induce febrile reactions, such as intravenous injections of typhoid vaccine, cannot be similarly classified because they are capable of converting a simple and local eczema into a generalized and acute variety. Such therapeutic devices are forms of protein shock and should only be used if used at all, in the treatment of, for example, established lichenized eruptions when methods of appeasement have been discarded at the proper time. Although this form of treatment is not without disadvantage and even risk, I am bound to say it has given results where other methods have failed.

Varicose Eczema

Every practitioner is familiar with the combination of eczema and varicose veins, a half-way house linking the endogenous and exogenous conception of the eczema process, as the following clinical phenomena clearly reveal. First, varicose veins are common, but only a few of those who suffer from them develop a complementary eczema. Therefore the presence of both varicose veins and eczema points to an endogenous eczema factor in that individual. Secondly, it is also constantly observed that if the varicose veins are successfully treated the eczema disappears. And, thirdly, it is possible to treat the varicose eczema successfully by suitable applications without interfering with the varix either by surgery or by injections. The interpretation of these facts seems to be as follows: the varix produces a *locus minoris resistentie* upon which, but only in a potentially eczematous subject, an eruption develops; but there is also a local or cellular dysfunction which can be overcome and set right by local treatment alone, despite the endogenous factor.

Eczematous Reactions

We can now pass under review certain paradoxical reactions observed in the more extensive forms of eczema. We are all familiar with the type which, beginning symmetrically on the legs, subsides or even clears up notwithstanding an extension into an acute form to other regions—the arms, for example. In these cases a process of autosensitization may be presumed whereby the skin has become sensitized to the products of its own damaged cells set free because the original eruption has been scratched or otherwise irritated. To satisfy the facts, and other hypotheses must in such cases concede the existence of a circulating agent which is carried to the skin and there provokes the eczema eruption. But under these circumstances all the skin areas should react in the same way at the same time, which does not happen. Therefore as certain portions of the skin recover as the result of treatment or spontaneously, while elsewhere the eruption extends or develops, we are entitled to infer that the skin is in a sense self-governing and can restore its integrity despite the continued action of the internal or humoral factor. Exogenous dermatitis, now to be considered, is that form of eczema in which the eruption is brought out by contact with one or several skin hazards—that is to say, certain external agents which are known to be capable of provoking an eczematous reaction by contact. The distribution will therefore usually be on the backs of the hands, fingers, and forearms. To this rule there are necessarily many exceptions, depending upon the kind of occupation and the nature of the skin hazard, of which a formidable list could easily be prepared from those in common use in the various industrial processes to-day. Nor do the circumstances of home life confer freedom from exogenous dermatitis, as witnessed by the housewife's hands, chapped and excoriated by contact with soap and water or other agents used for cleansing and similar purposes; or from the use of chemical fertilizers in the garden. In these cases there is some degree of the internal factor, otherwise all workmen and all housewives would become similarly affected. Nevertheless, as in this class of eruption the cause is clearly external, it is properly described as an exogenous or contact eczema.

Sometimes the skin is specifically sensitized to one agent, as in primula dermatitis. In such cases, because of an idiosyncrasy, the individual is permanently sensitized to the skin hazard.

Treatment of Eczema

From this it follows that the topical treatment of eczema is in all cases essential, and will usually take precedence over the general—which is logical, because we can see and treat the faulty skin and can directly observe its reactions. While there is no standard treatment for eczema as such, there are certain guiding principles, which may be summarized as follows. The eruption presents itself in an acute, subacute, or chronic phase, each calling for a different kind of local application. Thus in the acute phase decongestion of the inflamed skin by an evaporating lotion is required, whereas an ointment is usually contraindicated by reason of the heating effect of an occlusive dressing. In the middle or subacute period a paste is suitable, the powder incorporated in this paste rendering it permeable and allowing the passage through it of exudate. Finally, a stimulating ointment or small doses of x rays are employed in the chronic phase. From this it follows that where eczema is widely distributed, different regions may require different forms of topical treatment to accord with the various forms of local reaction. This design of treatment can be represented in the following framework.

Acute:—Lead-glycerin, or calamine lotion
↓
Oily calamine lotion
↓
Subacute:—Zinc paste
↓
Chronic:—Zinc paste with either tar solution or crude coal tar, 6% or x rays

The formula for the lead-glycerin lotion is as follows: glycerin of subacetate of lead, 1 oz.; glycerin, 1 oz.; and water to the pint. It is unfortunate that glycerin is in short supply, because we are thereby deprived of an invaluable remedy for which

there is no real substitute. Lead-glycerin lotion is applied as a moist dressing on white lint, which must be kept constantly wet. A word may be added concerning the form of superficial x-ray therapy prescribed for chronic rebellious eczema. This should be reserved for localized patches of refractory eruption, and especially for occupational dermatitis affecting the backs of the hands. One-half of a full dose—that is, one-half of the amount required to cause the hair to fall out—is given, and is repeated if necessary in four weeks' time. This treatment should, nevertheless, be entrusted only to those experienced in this very highly specialized branch of radiotherapy.

This is the positive approach to topical therapy. There is also the equally important negative—that is, the avoidance of those things which delay recovery or provoke a relapse. Scratching, the injudicious use of soap and water, the effects of sun and wind, which includes therapeutic ultra-violet irradiation, are all to be reduced or excluded so far as possible. In some cases small doses of a sedative may be called for to reduce the over-sensitive reaction to simple external stimuli. Rehabilitation has now become an integral part of modern treatment: the re-education of the skin is an essential to recovery, and this applies in particular to exogenous dermatitis. To resume work before all traces of the eruption have disappeared is to court further trouble; a period of convalescence adds considerably to the prospect of permanent recovery except where there is an idiosyncrasy which precludes any future contact with the specific injurious agent. This is no more than the application of those general principles of treatment which are fundamentally the same throughout all the branches of medicine.

VISUAL PHYSIOLOGY OF THE CINEMA*

BY

GEORGE H. BELL, B.Sc., M.D.

(From the Institute of Physiology, University of Glasgow)

The moving picture has in the past been used to a certain extent for educational purposes both in schools and in universities, and when photographic materials become available once more it is certain that there will be a very great exploitation of this teaching medium. The fighting Services and propaganda authorities have no doubt of the value of this dynamic method of illustration. It is axiomatic that the best way to learn about a thing is to study the thing itself; the next best is to study a motion picture, particularly a slow-motion picture, of it. The other available methods—hearing and reading, which have been so long our only alternatives—are certainly inferior. Since the cinema is likely to play an even larger part in our general environment than it does at present, it is important that medical people should have some elementary knowledge of the physiological problems of moving pictures.

Design of the Cinema

The student comes to the class-room to learn, and no unnecessary difficulties or distractions should be put in his way. The quality of the projection should therefore be better, if possible, than that attained in the commercial cinema. Fortunately a committee of the Society of Motion Picture Engineers (1941) has issued a series of recommendations regarding the proper use of 16-mm. equipment, as this size has been generally accepted as the standard for educational purposes. These recommendations are the basis of the present account of the technical design of the cinema.

The details of the picture can be clearly seen if the observer is seated not more than six screen-widths from the screen. A position too near the screen is not to be recommended, because, as a result of the great magnification of the photographic image, the picture on the screen—even when properly focused—lacks sharpness. It has been stated that efforts of accommodation made in attempts to improve the definition may fatigue the ciliary muscles. Flicker also tends to be prominent when too near the screen, but disappears when the observer moves back (Masterton and Kellogg, 1942). At the front of the class-room, where the screen appears largest, the roving movements of the eyes necessary to follow the action may

* Abstract of a lecture delivered in the Tennant Institute of Ophthalmology, Western Infirmary, Glasgow.

be excessive and are apt to produce fatigue. These excessive movements may, moreover, reveal flicker not seen when the gaze is steadily maintained. Flicker may be manifest on entering a theatre, but as a rule in a few minutes the sensation diminishes or disappears.

The screen should be filled by moving about the projector, which, with the usual 2-in. lens, will be $5\frac{1}{2}$ screen-widths from the screen. There will be one position in the room where the perspective of the projected picture is correct: since most 16-mm. pictures are taken with a 1-in. lens (or are reduced from 35 mm., which amounts to the same thing) this position is half-way between the projector and the screen. Other positions may give rise to error in the estimation of relative sizes of objects, but this does not seem to be important; the camera-man may use lenses of different focal lengths, and obviously the observer cannot be in the correct position for every one. It is important, however, not to sit too much to the side; at 40 degrees from the line at right angles to the screen the screen appears square, and this is not a tolerable amount of distortion (Tuttle, 1933). For school projection the viewing angle should not be more than 30 degrees.

The committee therefore recommends (a) that a picture-width equal to one-sixth of the distance from the farthest row of seats to the screen position should be adopted for class-room projection; (b) that no pupils should be seated closer to the screen than twice the picture-width; and (c) that no row of seats should be longer than its distance from the screen (Fig. 1).

FIG. 1

FIG. 2

FIG. 1.—Diagram of seating arrangement of class-room with mat screen of width W . The projector is situated at P . The thick line indicates the limit of the seating area.

FIG. 2.—Diagram of seating arrangement for a narrow room with a beaded screen.

(Modified from diagrams in the *Journal of the Society of Motion Picture Engineers*.)

The screen has an important influence on the seating arrangements. A screen with a mat surface—e.g., flat white paint—is 90% as bright at 30 degrees from the perpendicular as at 0 degree; no modification of the recommendations is necessary. Some screens have their surfaces coated with small glass beads. In this case most of the light is thrown back towards the projector even when it is at an angle to the screen. An observer on the centre line of the class-room sees a picture about four times as bright as that obtained with a mat screen, but the brightness falls off rapidly as he moves to the side: the maximum viewing angle should be 20 degrees. When an evenly illuminated beaded screen is observed from the front of the room one part of the screen may be very much brighter than the other parts; to reduce the variation of brightness to a tolerable degree no seat should be less than $2\frac{1}{2}$ screen-widths from such a screen (Fig. 2). Screens coated with fine particles of aluminium, with either a smooth or a rough finish, should never be used for class-room projection as they show a pronounced bright area, and, being colour-selective, they are not suitable for colour films.

In a square room (Fig. 1) the mat screen is undoubtedly the best, and is certainly the kind to use. The beaded type may be used in a long room, with the precautions mentioned (Fig. 2). It is necessary to point out what is so often forgotten—screens need to be kept clean. A screen which has deteriorated may waste up to half the light falling on it, as well as cause distraction when the image appears to move across mottled areas (Falge, 1931). Wandering of the attention of the spectators is diminished if the area around the screen is dull and featureless; the border of the screen is probably better grey than black.

It remains to decide the brightness of the projected picture which will allow the eyes to work at full efficiency (Projection Screen Brightness Committee, 1936). If the light is too weak picture quality suffers, contrast diminishes, high lights are weak and detail cannot be seen from the back row of seats. If there is too much light, graininess may become evident, high lights dazzle, and flicker become apparent. It has been found by trial that the desirable brightness corresponds to 10 foot-lamberts* with the projector running but with no film in the machine. Under these conditions, at a speed of 24 frames per second with a two-bladed shutter there will be an objectionable 48-cycle flicker. Under normal conditions, however, flicker is not noticeable, because the brightness-range of the picture is usually from 8 to 28% of that of the blank screen. The brightness may be increased by using two-bladed shutter in place of the three-bladed one often supplied whether flicker becomes obvious depends partly on the illuminance and partly on the projector design. Flicker and also film wear would be greatly reduced if a continuous instead of the present intermittent projection method were available; the optical difficulties are, however, considerable.

The required light output in lumens equals—

$$\frac{\text{Desired brightness}}{\text{Screen ref.}}$$

For example, a mat screen 3 ft. by 4 ft. with a reflection coefficient

$$\text{of } 0.75 \text{ needs a projector output of } \frac{10 \times 12}{0.75} = 160 \text{ lumens. It}$$

is expected that manufacturers will soon give values for their projectors. For ordinary class-rooms there will be no difficulty in obtaining adequate brightness with incandescent lamps, but when the screen size exceeds 8 or 9 ft. arc lighting may have to be used.

The quality of the picture suffers if the projection-room is not adequately darkened, but complete blackness is neither necessary nor advisable; a general room-light of 1/10 foot-candle (with which it is just possible to read newsprint) is not harmful, and may be appreciated for reasons of safety or of discipline.

The Illusion of Reality

Having dealt with some of the features in the design of the cinema, I should like to describe a few of the reactions on the spectators of what is presented to them on the screen. It is fair to say that most of the advances in film technique have been introduced to give the audience a greater feeling of reality. Mechanical improvements in cameras and projectors have made movement less jerky and have eliminated shake and flicker; development of radio technique has given us a sound accompaniment; photographic advances have improved tonal quality and have recently given us colour—surely a great step towards reality. We might well ask what will be missing from the complete illusion when stereoscopy is added, as it must be before very long.

The answer is that many things will be missing, the absence of which is not appreciated, because of the accommodating and uncritical qualities of the human mind. The silent films seem very strange to us now and would not stir our emotions to any degree though many of us can still recall how we were shocked when the films began to talk. We are accustomed to seeing pictures in black-and-white and we accept without question the absence of colour. To avoid undue mental shock colour has to be introduced gradually in the middle of a monochrome film. Disney's *Fantasia* was surely a riot of colour, but it began with rather severe shades of the orchestra in black and orange. Stranger still, when we see coloured films of natural scenery we are apt to describe them as unnatural when in fact the colour rendering is extremely good. The book *Film*, by Rudolf Arnheim (1933), is a most interesting example of this conservative attitude. Arnheim actually welcomes the photographic and physiological restrictions of the medium: the film cannot represent Nature accurately, and the more attempts to do so the less likely it is to be artistic; and, further, colour and stereoscopy are considered to be dangers to artistic presentations because they make the moving picture too natural.

* A lumen is the amount of light falling in one second on unit area placed at right angles to the direction of the light at unit distance from an international candle. The foot-candle is the unit of illumination equivalent to one lumen per square foot. The foot-lambert is the brightness of a surface emitting or reflecting one lumen per square foot.

The camera is single-eyed and therefore true vision of depth is possible, but the image projected on the flat screen gives us a lying of depth by variations in size and intensity, by perspective and parallax: a man walking away from the camera becomes smaller, less well-defined, and moves across the background. Occasionally I have noticed that viewing the screen with two eyes gives a smaller feeling of depth than does monocular vision—perhaps because both retinal images are the same. In the absence of stereoscopic perspectival excisions are sometimes rather obvious at the corner of a newspaper in front of a man's face may cut a little off. There is no doubt that stereoscopy is the most important factor in perception of depth (Washburn and Wright, 1938) and if it were added to cinematography a great step towards the complete illusion of reality would have been achieved. There is a short cut to stereoscopic vision: each eye must be given a slightly different view. A few stereoscopic moving pictures have been made and shown publicly. A number of methods are possible (Norling, 1941; Langlands, 1943), some of which do not even require the spectators to wear special apparatus over the eyes—rely on an amazing example of human ingenuity.

Although the eye and the camera are constructed on similar principles, and although the images on the retina and on the film are, so far as we know, very much the same, yet we do not see exactly what is projected on the retina. If I stretch out my hand it does not seem to grow bigger, in spite of the increase in the size of your retinal image. This peculiarity of vision which gives constancy of size and form has been called by Thouless (1931a, 1931b, 1932) phenomenal regression to the real object. A square card lying on a table in front of us is always seen as a compromise (a phenomenal shape) between the shape calculated from the laws of perspective (the stimulus shape) and the actual square (the real shape). The camera images and the projected images are faithful renderings of the stimulus shape, and may thus give rise to distortion. In cartoons it may be important to draw the shapes according to formal perspective but so that the resulting sensation is the same as that evoked by the actual objects. Regression depends on clues of depth; if, therefore, the illusion of depth is complete, as in stereoscopic cinematography, the image thrown on the screen should obey the laws of perspective. Since at present the illusion is not complete a compromise between the phenomenal and stimulus shapes would probably give the best results.

The eye readily rejects images that are obviously inappropriate—e.g., the image of a squinting eye. The eye, like the camera, can be focused accurately for only a small range (depth of focus) at any one time. Out-of-focus images are not normally seen; continuous adjustment of accommodation ensures that each plane is examined while in focus, so that the subjective impression is that the whole depth of the scene is in accurate focus. The disadvantage of camera vision has been overcome by multiplane photography in which successive planes are focused in turn and recorded without blurring of detail.

It is curious how soon after entering a cinema we forget the severe restriction of the visual field—at two screen-widths distant it is 28 degrees, at six widths only about 9 degrees. Attempts have been made to increase the size of the film and of the screen, but these have not been successful. The small field of vision makes it difficult to replace clues normally provided by the proprioceptive nerve endings. In a street scene we may be shown barrows being pushed uphill with obvious effort to give us a second-hand notion of the appropriate muscular sensation denied to us lounging in our seats. Sometimes the camera is made to look round (pan) so that we may be given a wider view; when the picture is projected we get the impression that the scenery is floating past. If the eye is fixed, movement of an external object from right to left causes movement of the retinal image from left to right, and we are aware that the object has moved. When the eye glances from left to right the retinal image again moves from left to right, but the external object does not appear to move and may not even be seen. The failure of reciprocity can be clearly seen if a neon lamp on a.c. mains is used as the test object (Bell, 1943, unpublished). It seems reasonable to deduce that proprioceptive impulses arising in the external eye muscles are responsible for the reduction of visual sensation during eye movements. Normally we take in a scene in a series of glances, but if the camera made glancing movements the projected picture would be very unsatisfactory, since our proprioceptors would be unaffected. In the present state of physiology it is hardly possible to imagine how artificial but

appropriate proprioceptive stimulation could be supplied to an audience.

We are thus a considerable distance on the road to the complete illusion of reality, but there are many problems yet to be solved. It seems to me that a great bar to improvement of film presentation lies in the multiplicity and complexity of the techniques employed in one moving picture. It may even be that if the technique for the perfect illusion were available it would be an impossible medium. The main difficulty would be to find a superhuman creative worker who would be first an artist and then a technical expert in matters tactile, olfactory, proprioceptive, and auditory, as well as in three-dimensional colour.

ENCEPHALOMYELITIS FOLLOWING VACCINATION IN FIFE

BY

G. MATTHEW FYFE, M.B., Ch.B., D.P.H.

Medical Officer of Health, Fife County

AND

J. B. FLEMING, M.D.

Medical Superintendent, Thornton Infectious Diseases Hospital

The three outbreaks of smallpox which occurred in Scotland during 1942—in Glasgow in May (32 cases), Methilhill, Fife, in August (29 cases), and in Edinburgh in October (36 cases)—were each followed in Fife by a public demand for vaccination. The vaccinal state of the public was low. It was estimated that in Methilhill only 20 to 30% of the population had been previously vaccinated; while at Cowdenbeath, a town in which one case of smallpox occurred at a late stage in the outbreak, between 40 and 50% had been vaccinated. The percentage of vaccinated infants in the county as a whole is normally 30.7. The number of people at all ages who received primary vaccination following upon the outbreaks was therefore in excess.

During the Glasgow outbreak free vaccination was offered in Fife through general medical practitioners, and no specific instructions were issued as to any method of insertion; but when cases at Methilhill were found to be suffering from an infection of high potency, and when one of them who had been vaccinated by the single-stroke method sickened with smallpox ten days later, instructions were given that three insertions be made 3/8 in. long and 1/8 in. apart. For the most part this method was followed, but it is known that some practitioners continued to employ the single-stroke method or undertook multiple scarification. It was not possible to collect accurate information regarding the sequelae of the methods used, but it was ascertained that severe local reactions and prostration more often followed the three-stroke method. This method was largely employed in the affected area, and absenteeism at the local coal-mines, which continued for an average of two days, rose from a normal level of 5% to 15%, and at a local emporium employing about 200 people from 0.5% to 6%.

In all, 54,698 doses of lymph were issued by the county public health department to private practitioners and to public clinics. Of these, 7,151 were obtained from a private firm immediately the presence of smallpox became known. The remainder came from the Government lymph establishment. Orders for lymph were placed daily, so that fresh material was always in use. Stocks were kept in refrigerators overnight.

On the whole, post-vaccinal disorders were of comparatively brief duration, and, although no reliable evidence was forthcoming that vaccination had in general a deleterious effect on health, the occurrence of 9 cases of encephalomyelitis following on vaccination gave rise to disquietude. Two had been vaccinated with lymph from the private firm and seven with Government lymph. The following table shows the relation of the cases to the number of vaccinations performed:

	Glasgow Outbreak	Methilhill Outbreak	Edinburgh Outbreak (Cowdenbeath)	Total
Public vaccination centres .. Docks, factories, collieries, hospitals, L.A. staffs, etc. ..	—	21,232	10,961	32,193
Medical practitioners, non- panel patients	—	3,466	431	3,897
Ditto, Panel patients (esti- mated)	1,360	19,081	5,657	26,098
Total	997	8,993	3,148	13,138
Cases of encephalomyelitis ..	2,357	52,772	20,197	75,326

All of the 9 patients were children of ages varying from 3 years to 17 years, and in each the vaccination had been a primary one. All were reported to have been in good health before vaccination, except one child who was suffering from whooping-cough, on account of which fact encephalitis following on whooping-cough could not be entirely discounted. The vaccination lesion was a single vesicle in each case, and was pursuing an apparently normal course. No information was obtained regarding the method of vaccination employed. Nervous symptoms occurred ten to twelve days after vaccination, at a time when the usual constitutional upset of vaccinia begins to subside.

In six cases the clinical findings pointed to a diagnosis of encephalitis, with headache, vomiting, and drowsiness or coma as the predominant features; four of these patients died. In two cases the symptoms and signs, localized to the spine, indicated a diagnosis of myelitis; both recovered rapidly. In one case the nervous complication took the form of an acute lymphocytic meningitis; recovery was rapid and complete.

The main features of the cases are summarized in the table opposite, but a clearer clinical picture will be conveyed by a brief summary of the case histories of the patients under our care.

Case I

A boy aged 3½. Primary vaccination on 11/10/42, before which he had had a slight cough. He sickened on 21/10/42, and on 22/10/42 he became drowsy. On admission (23/10/42): Temperature 98.4° F.; pulse 142; respirations 30. A poorly nourished, ill-looking child, listless, limp, and drowsy. When roused he was irritable, but was apparently clear mentally. There was flaccid paralysis of lower limbs with strongly extensor plantar reflexes; trismus present; pupils equal and reacted to light; squint present; follicular tonsillitis present and also cough of whooping-cough type. The child's condition gradually deteriorated, with rising temperature and pulse rate, drowsiness deepening to coma, and onset of spasticity of limbs, particularly noticeable in the flexor muscles of the arms. He died 48 hours after admission. Permission for necropsy was refused. Although the diagnosis of whooping-cough was reasonably certain on clinical grounds, *H. pertussis* was not grown on cough plate cultures exposed on the day before death.

Treatment.—From the time of admission he had 0.5 g. of sulphapyridine four-hourly. Twenty-four hours after admission he was given 20 c.cm. of antivaccinal horse serum (Lister Institute) intramuscularly.

Case II

A boy aged 10. Was vaccinated on 11/10/42 and became ill on 22/10/42 with headache and sleepiness. On 23/10/42 he was feverish, with headache, vomiting, and drowsiness. On 24/10/42 he became delirious and was admitted to hospital. On admission: T. 102.4° F., P. 124, R. 22. A sparely built boy, unconscious, restless, and emitting short high-pitched cries at intervals, especially when disturbed; incontinence of urine. Examination was difficult on account of restlessness; eyes normal; no spinal rigidity; plantar reflex flexor on right and doubtful on left; abdominal reflexes absent; tache cérébrale present; throat acutely inflamed. 25/10/42: Still drowsy, but much less irritable; trismus present; could be made to drink with difficulty; temperature normal. 26/10/42: Simple questions answered for first time since admission; left plantar reflex flexor; pulse rate 56. 29/10/42: Plantar reflexes flexor. 1/11/42: Both legs stiff. 2/11/42: Well in all respects.

Treatment.—A few hours after admission he was given 30 cc. of antivaccinal horse serum (Lister Institute)—23 c.cm. intravenously and 7 c.cm. intramuscularly. His mother, who had been vaccinated in infancy, revaccinated in 1927, and again on 11/10/42 gave a quantity of her blood on 25/10/42. The boy received 140 c.cm. of his mother's serum intramuscularly—60 c.cm. on 25/10/42 and 80 c.cm. on 26/10/42. The only drug used was a soneryl suppository as a sedative during the first night.

Case III

Boy aged 8. Was vaccinated on 12/10/42 and had fairly severe vaccinia from 19/10/42 to 21/10/42. From then he was in normal health until the evening of 24/10/42, when he became listless and drowsy. On 25/10/42 he was acutely ill with severe headache and drowsiness, temperature 104° F. On 26/10/42 he became delirious and had difficulty in speaking and drinking owing to trismus.

On admission (26/10/42): T. 100° F., P. 96, R. 20. A well-nourished boy, listless and drowsy; mentally clear when eyes normal; tendon reflexes normal; no rigidity of spine; abdominal reflexes diminished on left side; plantar reflexes flexor on right, extensor on left; throat mildly inflamed. 27/10/42: Coma had developed during the night; by midday he could be roused only with great difficulty; trismus present; abdominal reflexes absent on left side, diminished on right side; plantar reflexes extensor on left, doubtful extensor response on right. 29/10/42: Brighter mentally; severe spasticity of legs and left arm; tendon reflexes exaggerated; spastic tremor of left leg; extensor plantar reflexes both sides. 30/10/42: Less spasticity of legs; plantar reflexes flexor. 31/10/42: Temporary return of severe spasticity of legs. 1/11/42: Mentally alert; well, apart from stiffness of left leg.

Treatment.—On 27/10/42 blood was taken from his mother, who had been revaccinated on 12/10/42. The boy was given 180 c.cm. of his mother's serum—20 c.cm. intravenously and 80 c.cm. intramuscularly on 27/10/42, and 80 c.cm. intramuscularly on 28/10/42.

The salient features of Cases VII, VIII, and IX are given in the accompanying table. These three fatal cases were observed by us, but from the histories obtained there is no doubt regarding the diagnosis.

In all of the six cases described the picture is one of encephalitis, with headache, vomiting, and drowsiness or coma producing paralyzes, at first flaccid and later spastic. In two of the cases the upper motor neurones affected were not those related to the limbs, especially the lower limbs. In five cases positive Babinski signs were recorded at some time during the illness—in the sixth no mention is made of the being carried out. In the three cases seen by us trismus was a feature of the early stages of the disease, causing difficulty in drinking and speaking. In the two cases which recovered there was no evidence of residual weakness at the time of discharge from hospital, and five months later there was suggestion of mental or nervous disturbance.

We regard Cases IV and V as examples of post-vaccinal nervous complication in which the inflammation of the central nervous system is localized to the spinal cord. Encephalomyelitis is often referred to in the literature, but we can only find three references to post-vaccinal myelitis as a clinical entity (Zappert, quoted by Rolleston in *Acute Infectious Diseases*, 1940, p. 420; and McKenzie, *Proc. roy. Soc. State Med.*, 1936, 235. Inconclusive reference is made to a case in Report of the Committee on Vaccination, 1930).

Case IV

A healthy boy aged 10. Was vaccinated on 14/10/42 and became acutely ill on 26/10/42, with severe backache in the lower thoracic region and pain radiating round his side to the right subcostal region. He had slight headache and sickness on 28/10/42, and was admitted to hospital. On admission: T. 98° F., P. 112, R. 24. A strong, well-nourished boy, alert and bright mentally; no spinal rigidity with obvious "tripod" sign present; Kernig's sign positive; no nuchal rigidity, but any attempt to flex the neck even the cervical spine, produced acute pain in the lower thoracic region and sharp pain in the right subcostal area; abdominal reflexes absent; plantar reflexes flexor on right side and extensor on left side; tendon reflexes normal. The spinal rigidity gradually passed off during the next three days, and he was discharged on 4/11/42. He had had no drugs or immune serum.

Case V

A girl aged 6. Was vaccinated on 13/10/42, and became ill on the evening of 24/10/42 with nausea, listlessness, and later delirium. On admission (27/10/42): T. 97° F., P. 100, R. 20. A well-nourished, bright, and alert child; extreme stiffness and pain

movement of lower half of spine; no nuchal rigidity or stiffness of legs; plantar reflexes flexor on left and extensor on right. 8/10/42: Lumbar puncture; cerebrospinal fluid clear; 35 mononuclear cells per c.mm.; spine still stiff and painful in the lumbar region. 30/10/42: No stiffness of spine; left plantar reflex extensor. 1/11/42: Well in all respects; no weakness of legs. She was given no drugs or immune serum.

Acute myelitis of this type is unlikely to endanger life, and is therefore neither the gravity nor the importance of encephalitis. Severe backache is a common feature of severe vaccinia, and it seems probable that post-vaccinal myelitis occurs more frequently than is generally realized. Thus Dr. J. Veitch, Cowdenbeath, in a private communication informs us that in his practice during the vaccination campaign "several cases (males) previously unvaccinated complained of pain and

leg. 6/11/42: Child improving, but still severe stiffness of neck and spine; still very irritable; there was difficulty in inducing her to drink. 7/11/42: Much brighter and less stiffness of spine; stiffness of the left leg. 9/11/42: Well in all respects excepting marked stiffness of both legs; reflexes normal. 14/11/42: Discharged well.

Treatment.—On 4/11/42 blood was taken from the child's father, who had been revaccinated on 22/10/42. 140 c.cm. of the father's serum was given intramuscularly—40 c.cm. on 4/11/42, 80 c.cm. on 5/11/42, and 20 c.cm. early on 6/11/42. Starting at noon 5/11/42 with 1 g. and continuing with 0.5 g. four-hourly, 15 g. of sulphapyridine was given.

Case VI appears to be an example of post-vaccinal meningitis or meningo-encephalitis. An alternative diagnosis is benign lymphocytic choriomeningitis, a virus infection giving a

Table showing Principal Features of the Cases

Case	Age (yrs.) and Sex	Date of Vaccination (Primary)	Onset of Illness	Admission to Hospital	Leading Symptoms and Signs	Cerebrospinal Fluid	Final Diagnosis	Evidence of Concurrent Infection	Treatment	Result
I Methilhill	3½ M	11/10/42	21/10/42	23/10/42	Drowsiness; vomiting; paralysis of legs	Clear; pressure increased; Pandey's test pos.; 8 mononuclear cells per c.mm.	Encephalitis	Whooping-cough and follicular tonsillitis	Sulphapyridine 0.5 g. 4-hourly; 20 c.cm. antivaccinal horse serum on 24/10/42	Died 25/10/42
II Methilhill	10 M	11/10/42	22/10/42	24/10/42	Headache; drowsiness; delirium	Clear; pressure slightly increased; Pandey's test pos.; 60 mononuclears per c.mm.	"	Follicular tonsillitis	30 c.cm. antivaccinal horse serum; 140 c.cm. maternal serum	Recovered. Discharged 5/11/42
III Coal town of Balgonie	8 M	12/10/42	24/10/42	26/10/42	Headache; drowsiness; trismus	Clear; pressure slightly increased; Pandey's test neg.; 50 mononuclears per c.mm.	"	Mild tonsillitis and pharyngitis	180 c.cm. maternal serum	Recovered. Discharged 5/11/42
IV Markinch	10 M	14/10/42	26/10/42	28/10/42	Backache; neuritis; stiffness of spine	Clear; pressure slightly increased; Pandey's test neg.; 15 mononuclears per c.mm. Wassermann neg.	Myelitis	Nil	Lumbar puncture only	Recovered. Discharged 4/11/42
V Methilhill	6 F	13/10/42	24/10/42	27/10/42	Backache; stiffness of spine	Clear; pressure normal; Pandey's test neg.; 35 mononuclears per c.mm.	"	"	" " "	Recovered. Discharged 3/11/42
VI Coal town of Wemyss	5 F	22/10/42	3/11/42	4/11/42	Drowsiness; headache; spinal rigidity	Clear; pressure increased; 300 mononuclears per c.mm.	Lymphocytic meningitis	Tonsillitis and pharyngitis	140 c.cm. paternal serum; 15 g. sulphapyridine	Recovered. Discharged 14/11/42
VII Buckhaven	4½ F	11/10/42	22/10/42	—	Drowsiness; coma; flaccid paralysis of legs; Babinski's	Clear; pressure increased	Encephalitis	Rales all over chest	15 c.cm. paternal serum on 25/10/42	Died 26/10/42
VIII Buckhaven	3 M	11/10/42	22/10/42	—	Vomiting; drowsiness; coma	—	"	History of laryngitis at onset	—	Died 23/10/42
IX Cowdenbeath	17 F	18/11/42	30/11/42	1/12/42	Headache; vomiting; drowsiness; coma; spinal rigidity; Babinski's; hyperpyrexia; incontinence	Clear; pressure normal; sterile	"	Nil	Lumbar puncture only	Died 3/12/42

rigidity in the cervical spine on the tenth to twelfth day after vaccination." Discussing the various types of nervous sequelae of vaccinia, Rolleston (*loc. cit.*) refers to Zappert's description of a meningeal form simulating tuberculous meningitis. Case VI in our series falls into this category.

Case VI

A girl aged 5. Was vaccinated on 22/10/42, and was taken ill on 3/11/42 with drowsiness, headache, and backache. On admission (4/11/42): T. 98.6° F., P. 128, R. 26. A well-nourished child of spare build, rather pale and acutely ill. There was a tendency to drowsiness, but she was cross and irritable when disturbed; throat acutely inflamed; severe nuchal rigidity; Kernig's sign strongly positive. Abdominal plantar and tendon reflexes normal; eyes normal. Cerebrospinal fluid clear; pressure increased; 300 cells, mainly mononuclear, per c.mm. Bacteriologist's report: "Protein, 40 to 50 mg. per 100 c.cm.; sugar present but markedly reduced; Lange reaction, 1112110000; Wassermann reaction negative; no acid-fast bacilli or other organisms demonstrated." 5/11/42: Still acutely ill; severe spinal rigidity; tremor of left arm and

clinical picture similar to that of Case VI. This child, however, was much more seriously ill than any of the cases of benign lymphocytic choriomeningitis seen by us, and the chance of this relatively rare disease occurring within the usual period for post-vaccinal nervous complications is very remote. It is reasonable to assume that, occurring as it did twelve days after primary vaccination and being accompanied by tremor and spasticity of the limbs, the meningitis was produced by the same cause as that of post-vaccinal encephalitis. It is of interest to note that the fatal Cases I and VIII were those of second cousins.

Commentary

Immune serum was used in the treatment of the serious cases seen by us. Cases I and II had antivaccinal horse serum (Lister Institute), but there was not enough evidence to make any decision regarding its value. It produced no serum reaction in Case II, although 23 c.cm. was given intravenously. In Case I the horse serum was probably used too late to be

effective, and in any case the fatal issue was undoubtedly hastened, and possibly caused in part, by the whooping-cough.

It was fortunate that the parents had been revaccinated about the same time as their children, since a source of human immune serum was then readily available. Parental immune serum proved to be of great value when given in large doses—e.g., 140 c.cm. The procedure can be followed without serious risk of serum reaction. It appears to us that in Case VII the dosage of parental immune serum was inadequate and, as in Case I, given too late to be effective. The rapidity of the illness seems to indicate that immune serum must be given early and in large quantity to be successful. Thus, when Case III was admitted, the patient did not appear to be ill enough to justify serum treatment, and in several hours he became comatose. We were convinced at the time that his life had been endangered by the delay of 24 hours in starting serum therapy.

The success of immune serum in the treatment of post-vaccinal encephalitis suggests that it is the virus of the vaccinia which is the causal agent. There is no method of ascertaining the virus content of lymph, and vaccinia may produce all degrees of severity of constitutional upset, and, as shown in our cases, the nervous complications may vary widely. Why should occasional cases develop serious involvement of the nervous system? Are these infections arising from the unsterile nature of calf lymph? Another possible explanation is that the susceptibility of the nervous system to the vaccinia virus may be increased by the presence of concurrent infection. In support of this theory it appears to us to be significant that most of our cases showed evidence of acute upper respiratory infection. Thus Case I had clinical whooping-cough and follicular tonsillitis; Cases II, III, and VI had acute pharyngitis; Case VII had "rales in chest"; and Case VIII had a history of laryngitis. The findings at least suggest that the hazard of encephalitis during vaccinia is much greater when there is concomitant infection in the upper respiratory tract.

Post-vaccinal encephalitis is extremely rare in infancy. Therefore, so long as the danger of smallpox exists, vaccination should be urged in infancy. With modern speed and facility in travel there is nothing to indicate that this danger is likely to disappear.

When primary vaccination of children becomes unavoidable—e.g., during an epidemic of smallpox—it would be a wise precaution to insist on vaccinating or revaccinating the parents at the same time. By so doing a source of safe immune serum would be made readily available if required, and this could be given in large doses—e.g., as a transfusion of plasma on the first indication of cerebral involvement.

Summary

In the Fife outbreak of smallpox in 1942, 8 cases of vaccinal encephalomyelitis occurred among a group of 52,772 recently vaccinated persons and 1 case among a group of 20,197 persons. The incidence in both groups is high, particularly in the first—1 in 6,600.

The case mortality was 44%.

In six of the cases symptoms were entirely of cerebral origin and in two they were of spinal origin—apparently an uncommon manifestation. In one the symptoms were predominantly meningeal.

Much benefit was obtained through the prompt use of parental immune serum in large doses.

It is suggested that there may be a liability to onset of encephalomyelitis in unvaccinated persons suffering from acute infections of the upper respiratory tract.

Vaccination is urged in infancy in view of the risk of involvement of the nervous system in later years.

If primary vaccination of children becomes unavoidable steps should be taken to secure a source of immune serum as a precaution.

Speaking at the twentieth meeting of the German Dermatological Society last year, Conti (*Disch. med. Wschr.*, 1942, 68, 1230) said that it was hoped in the future to have a uniform specialist service attached to the health offices. The obligation to obtain treatment must be enforced more strictly. Thus, in the case of syphilis, the accepted salvarsan treatment was obligatory, but a patient was not forced to accept some therapeutic measures, such as cystoscopy, catheterization, dilatation of the urethra, and lumbar puncture. The duty of secrecy still existed, and it was laid down that a patient who had not refused treatment must not be notified by name.

PHENIODOL: A NEW CONTRAST MEDIUM FOR CHOLECYSTOGRAPHY

BY

F. H. KEMP, M.B., Ch.B., M.R.C.P., D.M.R.
(The Radcliffe Infirmary, Oxford)

The object of this communication is to introduce a contrast medium for cholecystography which is claimed to be better than tetraiodophenolphthalein.

Literature of the Phthaleins

Graham and Cole, in 1924, first succeeded in visualizing gall-bladder by means of a radiopaque substance excreted through the liver. They were influenced by the pharmacological studies of Abel and Rowntree (1909-10), who showed that phthaleins and some of their derivatives were mainly excreted in the bile. The first experiments were made with the acid and sodium salt of tetraiodophenolphthalein, but unfortunately the preparations proved toxic and some of their subjects died. Ultimately they achieved success with the calcium salt of tetrabromophenolphthalein. The drug was injected venously in doses of 5 to 5.5 g. in 40 c.cm. of distilled water and films were taken 7, 8, 24, and 32 hours afterwards. A second report (Graham, Cole, and Copher, 1924) showed that the sodium salt was better.

The possibilities of the new test aroused the keenest interest. Within a year other American workers—notably Carmichael and Counsellor (1924)—had confirmed its value. It was shown that the most common and most reliable sign of disease is dilatation of the gall-bladder to fill with the drug. However, patients experienced severe toxic reactions after the test, and as the dose had too small a margin of safety.

Meanwhile, Graham and his associates (1925) had continued their researches. They reported that the toxic effects of iodophenolphthalein were due to impurities, and they advocated this compound for clinical use owing to the difficulties of obtaining pure preparations. Shortly afterwards Whitaker and Milliken (1925) showed that a pure preparation of tetraiodophenolphthalein had definite advantages. There was little difference in the comparative toxicity of iodine and bromine compounds, the former was considered superior because in a dose of only about half the size necessary with the latter it gave a denser and more solid shadow. These findings were confirmed as a preparation of tetraiodophenolphthalein became available.

At first tetraiodophenolphthalein was given intravenously, some of the early workers were not entirely satisfied with the procedure and persisted with other methods. Stewart and his associates (1925) stated that a considerable number of persons experienced unpleasant reactions when it was given intravenously, much so, that in hospitals with which we are connected it was not deemed advisable to continue intravenous injections when all other methods of diagnosis had failed. For these purposes they preferred oral administration, and were supported by no less authorities than Carmichael and Moore (1925). Their view gradually gained support as the quality of the preparation improved, and nowadays oral administration is the method of choice.

With the oral method the majority of patients experienced unpleasant reactions. Some of them complained of its disagreeable taste, many have nausea, a few are sick, and many have diarrhoea. There seem to be differences in the severity of the reactions with various preparations in different localities. Meneses and Robinson (1938) tried to find a better preparation. They examined calcium, lithium, potassium, and magnesium salts of tetraiodophenolphthalein, but for various reasons were rejected except the magnesium salt. They found that a 5-g. dose of this salt gives a shadow of the same density as a 3.5 g. dose of the sodium salt of tetraiodophenolphthalein. More palatable and was less apt to produce reactions. In the use of the magnesium salt, 76% were symptom-free, only 12% had no symptoms after the sodium salt. This report was favourable to the manufacture of the magnesium salt was not taken up in this country.

Other Contrast Media

Attempts to produce other more suitable compounds have been recorded by Pribram (1927), who put forward iodized tophan as a contrast medium. It was sold in Germany under the name of biloptin. This substance gave good reliable contrast pictures; but though it was at first thought to be well tolerated, subsequent work showed that a large dose caused damage to the liver, and even with the necessary dose it was not unusual to find casts in the urine. Later, Pribram (1936) tested a derivative of quinoline containing iodine. This gave excellent pictures, rich in contrast, but on technical grounds it was not introduced commercially.

Dohrn and Diedrich (1940), working in the laboratory of Schering A.G., Berlin, tried to make a substance suitable for peroral administration which would be better tolerated than tetraiodophenolphthalein. They reported that they had tested a large number of synthetic compounds by estimating the iodine content of bile flowing from a biliary fistula in animals. One drug— β -(4-hydroxy-3:5-diiodophenyl)- α -phenyl-propionic acid—satisfied all required conditions.

The substance was given clinical trial by Kleiber (1940), who reported that it is an excellent, entirely harmless, well-tolerated peroral contrast medium which gives shadows superior to those obtainable by intravenous injection of tetraiodophenolphthalein. It is sold by Schering A.G. under the name biliselectan. Each dose of 3 g. of the active substance is put up in the form of sugar-coated granules.

Kleiber reported his findings after 55 cholecystographies. In 25 cases in which no gall-bladder shadow was found the examinations were controlled by means of intravenous tetraiodophenolphthalein, but a negative picture resulted in all. Of these 25 cases 24 were operated upon, and in each case a diagnosis of obstruction of the cystic duct was confirmed.

The British Preparation Pheniodol

Papers giving the chemical structure and some facts about the properties and clinical application of biliselectan reached this country in 1941, and Dr. W. Baker, working in the Dyson Perrin's Laboratory in Oxford, devised a method of preparing the substance, a certain quantity of which was available for preliminary experiments.

The free acid is a white crystalline powder which is insoluble in water. It is readily soluble in weak alkali, but in this form is extremely unpleasant to take. Prof. J. H. Burn of the University Department of Pharmacology reported that it was well tolerated by animals, with no signs of ill effects. In one experiment a bitch of 7 kg. weight received 3 g. of the drug by mouth. She was observed for 24 hours, during which time she displayed no symptoms. She was then killed and portions of the stomach, intestine, liver, and kidney were submitted for histological section. These tissues were all well preserved and showed no abnormality that could be detected by ordinary histological methods (Dr. A. H. T. Robb-Smith).

The first clinical trials were made with a small quantity of the preparation supplied by Dr. Baker. Three adults were each given a dose of 4.2 g. suspended in water or milk. They made no complaints other than a slight sensation of burning in the mouth, like the flavour of a radish. Films were taken in the usual manner at 10 o'clock on the morning after administration—i.e., 16 hours later. The drug seemed to have been completely absorbed in one case, as none was visible in the bowel, and only small amounts were unabsorbed in the other two. All three showed a dense shadow of the gall-bladder similar in appearance to that usually given with 4 g. of tetraiodophenolphthalein. Three other subjects were given doses of 5, 6, and 7.5 g. respectively. All three had diarrhoea and slight abdominal discomfort in the night. The shadows of the gall-bladder were no better than those given with 4.2 g.

As the results of these trials were satisfactory Dr. Baker sent in his report to the Medical Research Council, whose Therapeutic Trials Committee later asked me to undertake further

tests with preparations supplied by different firms. In the meantime it was decided that the drug should be known officially as pheniodol.

Pheniodol under Test

The preparations were submitted in powder form. With each dose of 4.2 g. instructions were sent to the wards that the powder was to be mixed and stirred into a glass of milk and to be taken instead of the usual preparation of tetraiodophenolphthalein on the evening before the examination. The results were most disappointing. Almost all the patients complained of an unpleasant taste and discomfort in the throat. Some had noticed that the preparation was lumpy and that the lumps tended to stick in the mouth and cause burning. Radiographs showed masses of unabsorbed drug in the bowel. It was clear that in the majority of cases the drug had not been properly mixed, but it seemed advisable to consider alternative methods of dispensing.

The symptoms can be easily explained. The drug is insoluble in water and soluble in weak alkali. In the soluble form it is very bitter to the taste, and when swallowed causes burning in the mouth and throat. When given as a suspension in milk or water there is a tendency for the powder to form lumps unless it is properly mixed. These small lumps tend to stick in the crevices of the mouth, pharynx, or oesophagus, where they are dissolved in the natural alkaline secretions. If the drug is carefully mixed into a paste and then stirred into milk there is seldom any complaint, very slight burning being readily relieved by a drink of water. If not given properly the patient may experience discomfort for hours, and is often sick.

In a second series of cases each dose was dispensed in 1 oz. of mucilage prepared by hand in the hospital dispensary. On the day before the examination the patient was given breakfast and lunch as usual, but no special fatty foods to empty the gall-bladder as some authorities advise. At 4 p.m. the patient had tea and toast or bread-and-jam without butter or margarine. He was encouraged to take sugar in his tea. The drug was given at 6 p.m. in a glass of milk. Films were taken 16 hours later.

The findings with three different preparations are summarized in the accompanying table. So far as could be ascertained all the preparations of different manufacture were similar.

	B.D.H.	Glaxo	Boots	Total
No. of tests	31	16	30	77
Unpleasant taste	16	6	21	43

Dense filling	24	12	23	59
Faint	3	1	—	4
No	4	3	7	14

Of those showing "No filling" the findings of a pathological lesion were verified at operation in ten cases, all being associated with stone. The others were not operated upon. Three of the cases showing a faint filling were associated with stone.

Analysis of Reactions

The patients' symptoms were analysed, with the following results: **Taste.**—Many patients noticed a slight burning sensation in the mouth and throat. A few complained of a horrid taste and others disliked the mucilage. It was clear that the method of dispensing was still at fault.

Nausea and Vomiting.—Nausea was associated with persistent burning in the throat. Only four patients vomited, and of these two were subsequently found to have gastric or duodenal ulceration with gastric stasis, and another was in the habit of vomiting frequently. In one case there was no explanation other than the taking of the drug. All four patients had slight abdominal discomfort. The drug must be a mild gastric irritant, especially when there is delay in emptying the stomach, and for this reason it is suggested that the patient should always drink a glass of water after taking the drug, which will tend to wash it towards the bottom of the stomach and so hasten its elimination.

Diarrhoea.—About a quarter of the patients had diarrhoea. In many cases this was only slight, but in others it was sufficient to interfere with sleep. In most instances the diarrhoea was probably related to variations in individual susceptibility to the drug as an intestinal irritant. Bigger doses are more liable to produce

diarrhoea, without significant improvement in the contrast of the radiographic image.

Pain on Micturition.—A small number of patients complained of slight burning on passing urine on the morning after administration. Two had slight suprapubic discomfort, which suggested irritation of the bladder. None of these showed any sign of renal damage.

The manufacturers interested in pheniodol have since carried out further research into the dispensing of the drug. One firm (Glaxo Laboratories Ltd.) submitted samples of the drug in the form of sugar-coated granules. I carried out further tests, and found that the preparation was very satisfactory providing that the patient was asked not to chew or suck them. The granules readily dissolve in the intestinal juices.

Another firm (British Drug Houses Ltd.) has prepared the drug in the form of a fine powder which is readily suspended in water or milk. This preparation is also very satisfactory, though sometimes the patient mentions some slight burning in the mouth and throat; but this is readily relieved by a drink of water.

Comment

Since the introduction of cholecystography we have learnt a great deal about the behaviour of the gall-bladder in health and disease. Though numerous reports testify to its value many doctors still do not realize that reliable results can be obtained only by careful attention to technique and interpretation. Before giving any opaque material a preliminary radiograph should be taken, for failure to do so may result in faulty diagnosis. Unless definite gall-stones are revealed the examination should always be completed.

The most reliable results are obtained by the intravenous method of administration, but this is seldom employed to-day on account of the liability of tetraiodophenolphthalein to cause unpleasant reactions, venous thrombosis, or sloughing of the tissues if any escapes from the vein. The oral method is simpler and the results are reliable in a large proportion of cases, but on account of the tendency of the sodium salt of tetraiodophenolphthalein to cause vomiting or diarrhoea the radiologist sometimes has difficulty in assessing whether enough of the drug has been absorbed. Rowden (1933) tried to avoid these difficulties by administering the drug in No. 3 gelatin capsules, which he himself filled so that the drug might be fresh. His procedure gives excellent results; but few people take the trouble to prepare the gelatin capsules, and most workers prefer to give the drug in fluid form. I hope that pheniodol will prove less troublesome and therefore more reliable, as I have tried to show in this paper.

Normal Cholecystography.—A dense well-filled gall-bladder shadow which is normal in size and shape and of uniform opacity and which contracts after a fatty meal to a much smaller size is almost always normal. Very occasionally gall-stones may be obscured by the density of the shadow and are revealed only by a film taken with the patient standing erect or by serial films of the emptying of the gall-bladder. More frequently, mistakes are made because the observer does not appreciate that the gall-bladder is seldom completely filled with the opaque medium, and so fails to realize that it is possible to report normal findings when a stone may be held in the ampulla of the gall-bladder or in Hartmann's pouch. Likewise it is generally assumed that stones in the cystic duct always cause no filling, whereas there may be several stones in the duct without impairment of filling, concentration, or emptying.

Faint Filling.—Even when technical standards are fully satisfied I doubt whether the opinion given by Graham and his associates (1925) can be upheld. They state that "the sensitiveness of cholecystography in revealing abnormalities of the gall-bladder is one of its most striking assets in the diagnosis of slight degrees of chronic cholecystitis"; or, in other words, slight degrees of chronic cholecystitis cause impairment of the ability of the gall-bladder to concentrate the drug. I believe that this view is incorrect, for I have seen two cases of chronic cholecystitis with gross inflammatory thickening of the walls of the gall-bladder which had shown no impairment of concentration of the drug. With the oral method, too many factors influence the absorption of the drug for us to state whether variations in its concentration in the gall-bladder are of functional significance, so that a faint filling should be

classified as normal unless it is shown to be constant at repeated examinations.

No Filling.—The most reliable sign of disease is no filling of the gall-bladder. In most cases this signifies either that the cystic duct is blocked by stone or mucus or that the gall-bladder is grossly diseased or full of stones. To be sure that there is no mistake the radiologist should check all factors influencing the absorption and elimination of the drug and should make certain that the films are properly centred and exposed. The test should never be conducted when the patient is jaundiced or when there are other clinical signs of hepatic insufficiency, for the medium is likely to induce further hepatic injury and the gall-bladder rarely fills. In less severe cases of liver disorder a satisfactory shadow is given if the gall-bladder is normal. There may be no filling if the patient is unable to absorb fats or if he has been on a fat-free diet for a long time.

In every case cholecystography should be followed by barium meal to show whether the stomach empties naturally and to exclude any organic disorder which may affect the significance of the findings.

Conclusions and Summary

Pheniodol is a reliable peroral cholecystographic medium. Suitable preparations in doses of 3 to 6 g. give a shadow of the gall-bladder similar in density and filling to the one obtained with 4 g. of tetraiodophenolphthalein. It is less objectionable to take, and seldom causes vomiting. Diarrhoea occurs in some cases, but not more often than with tetraiodophenolphthalein.

An account is given of the interpretation of oral cholecystography in the light of present-day knowledge.

I wish to thank the Medical Research Council for allowing me to carry out this investigation. I am indebted to Prof. L. J. Williams for his help with the clinical work and to Mr. F. H. Robinson of Glaxo Laboratories for his invaluable criticisms. Messrs. Glaxo Laboratories, the British Drug Houses, and Boots of Nottingham have supplied me with the different preparations of pheniodol. I gratefully acknowledge the help of Dr. J. F. Brailsford, who has taught me the principles of cholecystography.

A CASE OF CONVERSION HYSTERIA

BY

RANYARD WEST, M.D., M.R.C.P., D.Phil.
(Department of Psychology, University of Edinburgh)

We seldom see a case summary that shows in outline the actual course of a short and successful psycho-analytical treatment: a lot is said about psychotherapy in general, but very little about its methods and techniques. Here is such a case. I hope the technique explains itself. The actual conversational symptoms are unusual.

A. B., an insurance clerk aged 30, complained of increasing difficulty in drinking. He could drink water in the morning, though not easily. Later in the day fluid always "went the wrong way" and in consequence he dared not try to swallow. His trouble started four or five years previously, when he thoughtlessly bought some iced lemonade at a dance and choked himself so severely that he was in a panic and waiters had to rush to his assistance. Four days later, and after describing this incident to some friends, he was for the first time unable to swallow readily. The disability then steadily worsened. His medical student fiancée had recently expressed the opinion that he was suffering from a spasm of the throat from an inferiority complex.

A. B. was a very tall, gracious, and immaculate young man with a fresh fair complexion, rather anxious blue eyes, and a

minent and large lower jaw. His test swallowing of air involved no movement, but he performed it without difficulty. He pointed, quite truthfully, that his palate was anaesthetic to a normally quite stimulus. When he was given a glass of water he held it in his mouth, tilted it a lot, made much play with lip movements, got in the face, and swallowed small quantities with much apparent effort.

True to type, there were other symptoms behind the presenting case. The patient readily volunteered that he "wanted to confess fear": he had struggled against it since the age of 11. Before it time he had been fearless, especially in fighting, which he used to enjoy. From kindergarten days he had always fought upon the assumption that he would win. But at 11 he was involved in a fierce fight in the school wash-house. In the first the other boy did not wish to fight but A. B. did. The enemy fought very recklessly, but A. B. worked himself into a "tremendous fury" and at the end the other boy was "a nasty sight." In the second fight A. B. early received a glancing blow on the face near the jaw. Suddenly he felt he must run away or he would be "knocked to the ground." He acted on the impulse, and since then had never been able to hurt anyone or to stand anything approaching a row. Later, as an adult, unreasonable fear had become attached to carving, cliff-climbing, and other adventures in which he forced himself to accompany an "utterly fearless" fiancée. Above all, he feared the occurrence of a situation where honour demanded that he should fight—e.g., an insult offered to his young lady.

A. B.'s interests were connected with refined city life. He was capable, friendly, and humorous, and a Sunday-school superintendent. He described himself as likely to be a "perfect curate," and this occupation he has since adopted. But into his developing life about people there had crept an observant but peculiar interest in physiognomy. In his own mind he classified people into two types according to the shape of their jaws. Men or women of one, which he called the "aggressive" (meaning successfully aggressive) or "leader" type, had vertical ascending ramus to their mandibles and receding lower jaws with the upper front teeth more prominent than the lower. He held that, in contrast, a backward-sloping vertical ramus, prominent lower jaw, and protruding lower teeth, together with a small mouth, "caused" a recessive weakness of character. This "non-leader" type, into which the patient himself exactly fitted, also had thin lips and a small and quiet swallow, as opposed to the large mouth, full lips, large and noisy swallow of "leaders, children, and natural people." His fiancée was in this avowed category.

School associations were taken first. They led A. B. to remember an earlier incident in the school wash-house. The school bully had been publicly ducked in front of a yelling crowd, and "nearly drowned." He had been frightened by the sight itself and by the "lynching atmosphere." By free association from this sight A. B. next recaptured early fears of asphyxia—e.g., when a cushion was held over his face as a child and in an attack of whooping-cough. He was an only child. His mother (of "leader" type) had clouted him, his father (a "non-leader") grumbled and drank, and there were constant difficulties between the parents throughout his upbringing. Some alarming fantasies of drunken men hitting women, while he stood by terrified and powerless to intervene, led him to the recollection of actual attacks of fury with his father for upsetting his mother and making her cry. He had wanted to hit him.

A return to considering his contemporary fears, and especially the question, "Why could he never attack?" led him suddenly to the conviction that he had always felt that a blow on his jaw would be fatal. "They'd catch me there. And my jaw is so thin!" The discovery that his cowardice was due to an imagined inferiority increased his assurance; and A. B. now began to develop the themes, "If Father had only trained me I'd have been able to take care of myself," and, "Fighting is not bad fun if you're built that way." With some difficulty he managed to face in imagination the possibility of "administering physical correction in an extreme case on behalf of a lady." Then, partly freed from fear of disaster and spurred to a just cause, he imagined himself weighing in more heavily. With increasing gusto he went through the motions of buffeting a foe, to the accompaniment of appropriate remarks from an imagined audience: "Bravo, sir! Nice uppercut!" In the midst of this exercise he suddenly became very excited and exclaimed that something was broken. He had hit his opponent right on the point of the jaw. Immediately he saw a conservatory in which his father sat with his mother upon his knee. It was a well-remembered photograph from the family album, with Mummy in her long skirts that he used to peep under and a blouse with bones in the neck, and Daddy tired and retiring, "like an undeveloped twig, with his kindness and temper, lack of discipline with me and heavy-handedness with her." He was surprised they were so intimate.

At this point in his treatment there was a considerable change in his contemporary attitudes. With awkward colleagues he now required prayer to maintain his calm. He spat out aggressive remarks and then prayed for humility. He was no longer afraid

of physical consequences: the issue now was between passion and restraining principle. In the following session he disposed of an imaginary aggressor against his fiancée with mixed feelings of hatred and liking of the undertaking. To his intense satisfaction a return blow on his own "Achilles heel," the jaw, did not seem to hurt him. Then came a second crucial analytic hour. Feeling that "honour would attach to it," and with some reassurance from me about the physical effects, he first slapped in the face a man who was insulting his fiancée, and then—"Oh! I hate doing this!"—went for a burglar who was hitting his mother, smashed his head with a poker, and throttled him. While he was trying in vain to see "the real cause" of his anger, his mother's assailant changed into a drunken man. He struck at him wildly, pulled his hair, sobbed, and then hit him crash on the jaw, nose, and mouth. Asked to see the face of his adversary, he found he could not, because it had a "Guy Fawkes mask on." The scene was repeated by request, and this time the "blinding rage" was absent "unless he does something extreme, such as jump on her." Then, "Oh! I can get it against Father! Oh! don't make me do that! I hit him, smash him to pulp, there, where Mother had phlebitis when I was 24." He lay on the couch and sparred away in mid-air, while his exclamations reached a climax of excitement and tears.

The case did not require to be taken much further into "deep" analysis. At succeeding sessions A. B. discovered, behind his own aggressiveness, fears that his father would in his turn attack him. He imagined himself a baby and his father lurching against him "as if in a sudden impulse of anger." Again, as quite a young child he had got a fish-bone stuck in his throat, and his father had apparently held his head under the tap as a remedy ("He might go on and I'd be powerless to stop him"). In reliving the incident he felt frustrated, hopeless, then acquiescent. Besides thus being at once an object and a source of aggressiveness, his father was associated with the forbidding of all pleasure. He had emphasized every risk in life, deliberately those of hitting and drinking (e.g., from public fountains), and by unintentional implication all those attendant upon personal desires. Oral pleasures had always been valued highly by this patient. Beneath his resentments against his father was much love for him, with many happy memories. But his father had been inferior in character to his mother, and A. B., with his weak character, deceptive jaw, and erring mouth, resembled his father.

The first beneficial effects of recapturing his "death wish" against his father was that A. B. developed a new efficiency at squash rackets. But after tracing all his fears to his complicated relations with his father—resentment, jealousy, identification in type, and underlying love—he felt that he could swallow as well as hit, and that, at least in the latter pleasure, there were few restrictions to the indulgence of his adult desires. He thereupon drank water without difficulty; and shortly afterwards he drank beer readily enough at his pre-marital bachelor celebrations.

A short review of the differences between adult and childhood aims closed the analysis at the 40th session. A. B. threw off the legacy with which the inability of his real father to lead him and to forgive and discipline his passions had left him. He was able to meet his adult requirements through a revaluation of aim and a reliance upon that "something more than Father" which chimed with his religious convictions.

Medical Memoranda

An Unusual Diphtheria Infection

Diphtheria infection of the mouth, anus, and genitals is not common, and its occurrence as a complication of childbirth and the puerperium must be rare. Faucial diphtheria in the newborn appears to be even more unusual. Rolleston (1939) was able to collect 12 cases (including only one personal case) of faucial diphtheria in the first two months of life. A clinical sequence of those two rarities is herewith recorded.

CASE HISTORY

Mrs. A., aged 24, was admitted to Thornton Isolation Hospital at 1.30 a.m. on July 29, 1941; temperature 101° F., pulse 144, respirations 28. She was extremely exhausted and pale, and looked gravely ill. She had been in poor health for some time. About July 26 she began to have discomfort in the mouth, followed by difficulty in swallowing and discomfort at the anus on the 27th. She was confined on July 28. Examination revealed an extensive thick grey membrane firmly adherent to the floor of the mouth, extending from the root of the tongue forward to the edentulous lower gum and also lining the sulcus between the gum and lower lip. The throat was acutely inflamed but showed no membrane. The submaxillary and submental glands were severely swollen. The anus and an area within a 2-in. radius were acutely inflamed and covered with thin grey slough or membrane. The membrane could be easily removed with a swab, leaving a raw wound similar to a burn a few days old. On each side of the vulva in the sulcus between the labium majus

and labium minus there were raised indurated areas of inflammation about 1 in. by 1½ in. covered with thin grey adherent membrane. Smears taken from the mouth showed no evidence of Vincent's angina. Swabs and pieces of membrane were later reported to reveal the presence of the true diphtheria bacillus.

At the time of admission 48,000 units of diphtheria antitoxin were given intravenously. On July 31 she was still dangerously ill. The buccal membrane was loosening. There was an area of deep inflammation in the right buttock. The vulvar membrane had now extended into the vagina and over the urethral meatus. There was retention of urine. Sulphanilamide 0.5 g. was given four-hourly and one pint of glucose and saline intravenously. On Aug. 5 she was still desperately ill, though the membrane in mouth and vulva had now cleared. She was given a transfusion of 18 oz. of citrated blood. Henceforth she improved steadily. The vulva did not heal until Aug. 18; the urine was not free from albumin until the 28th; her temperature did not settle until Sept. 9, and her pulse rate did not remain below 100 per minute until Sept. 15. There were no nervous complications. She was allowed up on Sept. 19 and was discharged on Sept. 22. Large doses of vitamins B and C and ferrous sulphate were given from the first week.

Mrs. A.'s baby, aged 7 days, male, was admitted on Aug. 4, 1941, with a history of nasal discharge since Aug. 3. On admission at 5 p.m. the baby's general health was fairly good; temperature 98° F. There was a napkin rash on the buttocks. The baby had a purulent nasal discharge and both tonsils were covered by white membrane. The cervical glands were slightly enlarged. 8,000 units of diphtheria antitoxin were given intramuscularly. A throat swab and a nasal swab each gave a culture of the true diphtheria bacillus of intermediate type. The throat was not clear of membrane till Aug. 6, and throat swabs were negative during the third week. In spite of the absence of nasal discharge from the second week, negative swabs from the nose were not obtained till Sept. 14. Apart from an intercurrent bronchiolitis on Aug. 30, which cleared in three days with sulphapyridine, the baby thrived, and was discharged on Sept. 16, having gained 2 lb. while in hospital.

A few days after the baby was admitted its aunt, aged 30, was also admitted suffering from faucial diphtheria. She gave a history of direct contact with the baby, and her infection also was of the intermediate type. She made an uneventful recovery.

Thornion, Fife.

Mastoiditis without Middle-ear Signs

The following case may be thought interesting enough to merit publication:

A girl aged 6 came to hospital on May 18, 1943, with a letter from her family doctor stating that she had had her tonsils and adenoids removed six weeks before, had had an attack of measles two weeks before, and that there was now a slight swelling behind the left ear.

Examination of the tympanic membrane showed that it was white and that the malleus was not even injected. A slight swelling was present behind the ear. Her temperature was 99.8° F. On May 19 I made an incision over the mastoid process and found the subcutaneous tissue much increased in thickness. I then performed a mastoid operation, dealing only with the mastoid and not touching the middle ear, but removing the bridge of bone over the external semicircular canal. On removing the bone over the antrum thick yellow pus flowed out in profusion. The bone over the dura in the upper and posterior angle of the wound was absent, and the dura itself was covered with granulation tissue. Further removal of bone showed that the cells of the mastoid down to the tip were full of thick pus. The bone over the lateral sinus was removed, and the lateral sinus was found to be normal; there was no pus in the middle ear. I treated the cavity with 1 in 20 carbolic acid followed by industrial alcohol, and then filled the wound with sulphacetamide (albicid) cream. Undermining the skin so that the thick subcutaneous tissue could fall into the wound, I sutured the skin completely except for a small aperture at the lower angle, into which I inserted a long and a short drainage tube.

The after-treatment consisted of the injection of 2 c.cm. of mercurochrome 5% in 20% alcohol four-hourly for three days, and acriviolet 1% in 20% alcohol four-hourly for one day, the tubes being removed on the fifth day. Sulphanilamide was given four-hourly every day till June 1, with one Benerva vitamin B₁ tablet, and half a teaspoonful of sodium bicarbonate, on account of the absence of bone over the dura, which was covered with granulations. After the tubes were removed the fistula was dressed with sulphacetamide paste and the wound was strapped once a day, and the patient was given six ascorbic acid tablets daily.

The evening temperature after the operation was the same as on admission (99.8°). On the second and third evenings it was 99° F., and during the rest of her stay in hospital was normal. She made an uneventful recovery, and was discharged on June 15, the twenty-seventh day after the operation.

The only explanation I can give of the normal tympanic membrane and middle ear is the presence of a tympanic dam, which Heath (1919) describes.

Reviews

LECTURES TO THE LAITY

The March of Medicine. The New York Academy of Medicine Lectures to the Laity, 1942. (Pp. 217. 16s. 6d.) New York: Columbia University Press; London: Oxford University Press. 1943.

The March of Medicine is the title of the seventh series lectures given to non-medical audiences at the New York Academy of Medicine. The selected subjects—tuberculosis, medical psychology, and nutrition—are precisely those of topical interest to the educated public, and each of them admirably handled. Dr. J. A. Miller shows clearly how there has been the advance in knowledge of the pathology and clinical course of tuberculosis, and how intermittent has been the progress in control of the disease. Tuberculin, over-feeding, gold therapy, and various other methods have had their ups and failed; solid advance has chiefly been in the environmental factor and the intervention of the surgeon. X rays have greatly aided diagnosis, but have also revealed fresh difficulties in the way of its achievement. Despite all these drawbacks mortality was steadily falling until the outbreak of this war. That it should be rising again now proves the prime importance of environmental conditions. Yet "tuberculosis still confronts us as a major challenge."

Dr. Tracy Putnam's lecture on the brain and the mind is an interesting criticism by a neurosurgeon of T. H. Huxley's conception of man as a "conscious automaton." He shows that behaviourism yields meagre data compared with those of psychological procedures. Even the naive impressions and judgments of any untrained man are better able to predict what a given normal individual will do in a given circumstance than are the formulas at present deducible from what is known of the physiology and pathology of the brain. And Dr. Putnam points out, the exploration of the unconscious has still further widened the gap. This is followed by a lecture on the Freudian epoch by Dr. A. A. Brill, himself the product of that epoch in the United States. We all know how Freud's methods started from the study of hysteria; it is less well known how deeply he was influenced by the philosophy of Descartes. As a historical review of Freud's progress his lecture is excellent. Dr. Gesell makes a gallant if unsuccessful attempt to explain the genesis of genius, though he has some entertaining comments to make by the way on mental growth in childhood. Dr. Norman Jolliffe has an easier theme in the history of the B vitamins. We are glad to see that he gives the correct date—1906—for the first contribution from Gow Hopkins on "accessory food factors," as this is so often overlooked in the attention given to his later papers; also due recognition is given to Casimir Funk's crystallization and conception of deficiency diseases. Because Funk regarded vitamins as amine bodies, the importance of his generalization is often forgotten.

Dr. A. I. Carlson concludes the series by a talk entitled "The Newer Knowledge of Nutrition," and asks, "How much of it is knowledge?" He vigorously sifts the grain from the chaff. Like every scientific advance with a popular appeal the subject of vitamins has been clogged by a good deal of pseudo-science; endocrinology has only recently been able to purge itself of most of such encumbrances. His trenchant criticism of humbug and overstatement, which are apparently more rife in the U.S.A. than in this country, is salutary reading.

QUEEN CHARLOTTE'S TEXTBOOK OF OBSTETRICS

The Queen Charlotte's Textbook of Obstetrics. Sixth edition. By Members of the Clinical Staff of the Hospital. (Pp. 577; illustrated.) London: J. and A. Churchill. 1943.

With each new edition this book goes from strength to strength. The authors and publishers are to be congratulated on the excellence of the new and sixth edition, which ranks as one of the best textbooks on midwifery available in English. The teaching is direct, concise, and reasoned. The authors state what they believe and practise and why they believe so, and for the most part they teach sound orthodox obstetric principles and methods. The newly established diagnostic department at Queen Charlotte's is directed by Dr. E. R. Williams, who has rewritten the radiological section so

new edition. With the material at his disposal and the close co-operation of the clinical staff it is to be hoped and expected that important contributions will be made from this new department, especially on the subject of x-ray pelvimetry. Sections of the book which are exceptionally good deal with abortion, hyperemesis, sepsis, disproportion, abdominal pain, and the baby. There is one minor criticism. When methods practised at Queen Charlotte's are described they could well be supported by reference to results obtained at that institution. Results obtained elsewhere are irrelevant except as a basis for comparison. For example, in describing eclampsia and its prognosis reference is made to the report of the London Committee, 1922, in which the maternal mortality was recorded at the appalling figure of 22%, but no idea was given of how effective is the treatment the authors advise and practise. On the other hand, in discussing breech deliveries the hospital results are given. They are not good, and the section would have its value enhanced rather than weakened if this fact were freely admitted and methods by which results could be improved were discussed. It is not enough to assume and declare that "a relatively high proportion of stillbirths is unavoidable in cases of breech presentation." This is not the way of progress.

The posterior position is not well handled. As all who practise obstetrics are well aware, it is a common source of trouble to both the general practitioner and the consultant. Failed forceps, foetal deaths, foetal injuries, maternal morbidity and on occasions mortality, are so frequently due to the undiagnosed or even the diagnosed posterior position. For this reason one would expect a thorough discussion on the handling of such cases. The authors have taken the easy way out by dealing only with those cases in which full dilatation is present. They constitute a minority of those which cause trouble, and a fuller discussion of the subject is essential.

Apart from these minor points for criticism the book is a splendid one.

BIOCHEMISTRY

Laboratory Directions in Biochemistry. By Victor C. Myers, Ph.D., D.Sc. (Pp. 258, 18s.) London: Henry Kimpton.

The Dynamic State of Body Constituents. By Rudolf Schoenheimer, M.D. (10s.) Oxford University Press.

Laboratory Directions in Biochemistry is a collection of class sheets of the author's practical class in loose-leaf plastic binding. Approximately half of the 288 pages are left blank for the student's notes. There is no index, explanation of the directions is rarely given, and attendance at the author's lectures and demonstrations is assumed. The book is therefore of little value outside the author's school. There are illustrations of apparatus found in every laboratory however ill equipped—e.g., a basin and burette arranged for titration; and yet in a detailed description of the use of the du Noüy torsion balance, with references to the various parts by letter, the reader is directed to Morse's *Applied Biochemistry* for the illustration! The course is an extensive one, too long for medical students in this country and too medical for science students. The actual directions are clear, but usually they are just orders without explanation. This book is probably invaluable for the author's own students, but the reviewer cannot recommend it for use in this country.

The three Dunham Lectures incorporated in Dr. Schoenheimer's book give a clear and stimulating account of the recent employment of isotopes in the study of metabolic processes. The theme throughout the three lectures is, "All constituents of living matter, whether functional or structural, are in a steady state of rapid flux." The evidence is impressive. With the bibliography and index provided the book makes an excellent survey which can be confidently recommended to all interested in this topic.

A PERENNIAL

The Medical Annual, 1943. Edited by Sir Henry Tidy, K.B.E., M.D., F.R.C.P., and A. Rendle Short, M.D., R.S., F.R.C.S. (Pp. 432; illustrated, 25s. net.) Bristol: John Wright and Sons; London: Simpkin Marshall.

The *Medical Annual* for 1943 appeared in the second half of this year, and it is probable that the faithful many have already got their copies of this excellent yearly publication, edited jointly by Sir Henry Tidy and Prof. Rendle Short, supported by a first-class team of contributors.

Problems of war medicine and surgery are given full consideration. The subject of burns is dealt with in two full and excellently illustrated articles by Cecil P. G. Wakeley and by Sir Harold Gillies and J. B. Cuthbert. The former includes an instructive whole-page plate illustrating a section of the skin and the various levels of burn destruction. Gillies and Cuthbert show some remarkable pictures of "pollicization" of the index finger in a case in which a burn had destroyed the thumb. A well-documented article (there are 113 references) under the title of "Chemotherapy of Bacterial Invasion" is contributed by R. St. A. Heathcote, who gives a useful review of antibacterial products of fungi and of bacteria and of the sulphonamides. Major-Gen. L. T. Poole and Lieut.-Col. H. J. Bensted contribute excellent accounts of typhus and of yellow fever. These are but a few of the good things among much that is excellent. There are one or two points that might call for comment. We could not find any reference to sandfly fever or infective hepatitis, and perhaps space could be given every year to an article under the heading of "vital statistics." The very well written survey of "legal decisions" seems to us to be too long in these days of paper shortage. Another encroachment on paper is made by the list of appointments under the contributors' names at the beginning of the volume. Some of them, so to say, go all "Who's Who"; several modestly occupy two lines only with name and appointments; the longest is eleven lines, occupying just on 1½ in.

As all its readers know, the *Medical Annual* gives a fair amount of space to advertisements, thus affording useful information to the practising doctor, who possibly looks upon the inclusion of an advertisement in the *Annual* as carrying with it some mark of approval: if this is the case, we should like to see a little more sifting of the bad from the good.

Notes on Books

Dr. MYRTLE B. MCGRAW has usefully collected her studies of the past few years into one volume, and in *The Neuromuscular Maturation of the Human Infant* she tells in some detail the fascinating story of normal child development with reference to structural development of the controlling mechanism. Some of her work has already been noted in these columns, and it should be made clear that the present volume is a new book and not merely a collection of reprints, though it is obvious that the author has drawn widely on her previously published papers. Studies of neonatal behaviour, the development of neuromotor activities, and some aspects of early sensory development occupy the bulk of the book. The opening chapter on structural foundations of behaviour, based largely on the work of the late Dr. F. Tilney and of Dr. J. LeRoy Conel, is too compressed for readers unfamiliar with modern work on intimate brain structure. The final section, on maturation and learning, is full of interest for all concerned in educational theory and practice—of the pre-school child more particularly. The book concludes: "Neurologists tell us that man does not begin to use all the cells in the cerebral cortex. An optimum educational system may be able to tap some of these reserve neural potentials." Altogether this is a valuable contribution to the field of educational psychology in the early stages of life. It is published in this country by the Oxford University Press at 13s. 6d.

The Natural Development of the Child, by AGATHA H. BOWLEY, Ph.D., of the Leicester School Psychological Service, was noticed in these columns soon after it appeared in May, 1942, with particular commendation of the final chapter on children's reactions to the war. This chapter has been expanded in the second edition by some further material illustrating the spontaneous opinions of school children about certain aspects of the present war. The publishers are E. and S. Livingstone of Teviot Place, Edinburgh, and the price is 8s. 6d., plus 5d. for postage.

Oliver and Boyd Ltd. have published at 2s., on behalf of the Imperial Bureau of Animal Breeding and Genetics, a pamphlet, *Gestation Periods: A Table and Bibliography*, compiled by J. H. KENNETH. The table gives the average gestation period in days for each of the animals listed in alphabetical order, with minimum and maximum for some of the animals, and with each item there is a reference number to the corresponding entry in the bibliography. This compilation does not include any comments.

The Famine Relief Committee, 67, Brook Street, W.1, has published a pamphlet, price 2d., entitled *A Year's Work*, giving an account of efforts to obtain permission for controlled and limited food relief in German-occupied countries. The committee also issues a leaflet on the present food situation in Belgium by its Advisory Medical Council, of which Lord Horder is chairman.

EPIDEMIC INFECTIVE HEPATITIS

Among infections that have given rise to special interest during this war, epidemic hepatitis stands out. Various called "epidemic hepatitis," "common infective jaundice," "epidemic catarrhal jaundice," "epidemic jaundice," "acute infective hepatitis," the disease was attracting the attention of numerous investigators in the immediate pre-war period. In an article in this *Journal* in 1937¹ Hugh Barber observed that in recent years sporadic cases of what he called "infective hepatic jaundice" had been common in South Derbyshire. Before the last war Cockayne² had differentiated the milder type of epidemic jaundice from the severer form found in 1914 to be due to infection with the *Leptospira icterohaemorrhagiae*. Differentiation was carried further by Hurst and Simpson,³ who separated catarrhal jaundice from infective hepatic jaundice; but their view has since been challenged. From evidence that was summarized in an annotation three years ago⁴ it appears that the condition discussed is an acute hepatitis, is infective, and often appears in epidemic form. Perhaps, therefore, the most comprehensive descriptive term would be "epidemic infective hepatitis," the word "jaundice" being dropped, as it is but a variable symptom of the disease. At present the infective agent is believed to be a virus.

In his interesting description of an outbreak in the Lavant valley in Sussex J. L. Newman⁵ observed that unless the disease was known to be prevalent the diagnosis might offer difficulty. One of his patients, for example, began the illness with rigors, was delirious, vomited, and had a temperature of 100° F.; pneumonia was suspected, the patient becoming jaundiced on the fourth day. In other cases the early clinical picture may resemble that of meningitis. The onset may be gradual or acute, with fever, nausea, vomiting, abdominal pain, and leucopenia. According to Barber jaundice usually appears the day after the onset. In the cases recorded by Newman⁵ and by Evans⁶ jaundice appeared at any time from the first to the twenty-eighth day after onset, a not uncommon time being 7 to 9 days after. In a series of patients (about 180) described by Hallgren⁷ the pre-icteric period averaged about 6 days, with a range from 1 to 14 days. It is noteworthy that over 8% of his cases had rigors, and pains in the head and limbs were common symptoms. The icteric stage lasted about three weeks, and it was about three weeks from the onset before the temperature was normal. In some cases the serum bilirubin had not returned completely to normal by the end of three months. The higher

the serum bilirubin in the early stages, the longer the illness was likely to last. Loss of weight, which averaged about 2 kilos, was at its height in the third week, and it was some 7 weeks before weight was regained. Owing to the fact that these patients had tuberculosis it was difficult to determine the mortality, but it is estimated at less than 1%. As Evans⁶ points out, acute infective hepatitis often entails several weeks of invalidism, and he also noted that the red-cell sedimentation rate may remain elevated for some weeks after an attack—even a mild one. Cameron⁸ stresses the importance of treating the condition as a serious disease of the liver. In necropsies of four cases (not in his own series) he found microscopical changes of subacute necrosis in the liver, but no macroscopic or microscopical changes in the biliary tract of two of them. Most of these recent descriptions of the disease confirm the accurate observations made thirteen years ago by W. N. Pickles,⁹ who gave an account of 250 cases of "epidemic jaundice" in Wensleydale in the North Riding of Yorkshire. Pickles described a pre-icteric stage lasting from 4 to 10 days, with loss of weight, nausea, vomiting, and pains in the back and limbs as symptoms. In his cases the icteric stage usually lasted 14 days, but occasionally longer. In this paper Pickles refers to the surprise he felt when, as a newly qualified assistant, he encountered an epidemic of jaundice in 1910—a condition not referred to in his medical school or textbooks. His principal, however, informed him that frequent epidemics had occurred in his 30 years of practice, which shows that the disease has been with us for at least 60 years.

Among the points about which exact information is wanted are the incubation period, the duration of infectivity, the infecting agent, the method of spread, and measures of prevention. In his paper of 1930 Pickles concluded that the incubation period varied from 26 to 35 days, that the period of infectivity was probably short, and that the method of spread was respiratory from case to case. Apart from Glover and Wilson,¹⁰ who, as the result of their observations of an explosive outbreak in a small country town, gave the incubation period as 3 to 4 days, most observers agree that the period is a long one. Newman's⁵ instances of the schoolmaster, "Mr. Raven," who went to school while feeling ill and left the same day, infecting four children at school as well as his wife, made it fairly certain that incubation periods in these cases were 24, 29, 30, and 31 days respectively. An incubation period of from 3 to 5 weeks was given by McFarlan.¹¹ In the institutional outbreaks recorded by Hallgren the statistical range of the incubation period was 34 to 52 days, although periods as short as 28 days were actually observed. The duration of infectivity is uncertain. According to Lisney¹² patients are infective during the incubation period; Pickles believes that the infective period is usually short and that isolation of the sick person for a fortnight is long enough.

The observations of numerous careful workers show that infection spreads mainly as a result of contact. That cases appear in crops argues against water-borne or milk-borne infection. But only "the most casual contact" was noted

by Bashford,¹³ and Newman² points out the difficulty of explaining serial infection in families on the basis of droplet or air-borne infection. Evans,⁶ noticing the frequency with which nurses became infected by looking after patients, suggested that the virus may be present in faeces or urine. In this connexion Hallgren⁷ gives evidence of the spread of infection by contaminated water. Here the characteristic of the epidemic in a sanatorium with a population of about 550 was its explosive nature. When the local water supply was investigated it was found to be contaminated by a leak from the main sewer. When this contamination was brought under control the epidemic ceased. No case of jaundice or hepatitis was found among the pigs raised on the offal from the sanatorium kitchen, and indeed there is little evidence to support Andersen's suggestion¹⁴ that the pig may act as the animal host for an epidemic of infective jaundice. It may be recalled that in the water-borne epidemic of "catarrhal" jaundice described by R. Fraser¹⁵ the jaundice outbreak was preceded by an outbreak of gastroenteritis 2 or 3 weeks before, affecting practically all of 520 students. Hallgren also mentions that epidemics of jaundice in diabetic clinics may have been caused by inoculation with infected instruments in the laboratory. Bigger¹⁶ has suggested that epidemics of jaundice in V.D. clinics may be due to the transmission of the virus from patient to patient in the syringes used for injecting arsenic preparations. Nevertheless it should be remembered that patients in clinics come into close contact with each other, and that both diabetics and syphilitics have vulnerable livers. It seems, therefore, that infective hepatitis usually spreads from case to case, and also that occasionally the virus may find its way into the water supply, giving rise to explosive outbreaks of infection. In this connexion the efficacy of methods of water purification in controlling virus infections may well be reviewed.¹⁷

ANTIDOTES TO ARSENIC

There has lately been an increase in the number of patients suffering from symptoms of arsenical intoxication as a result of antisyphilitic treatment. The first published work which indicated the mechanism of arsenical poisoning was that of Voegtlin, Dyer, and Leonard¹⁸ in 1923; they showed that the action of arsenic on protoplasm was due to organic sulphur compounds containing the sulphur in the mercaptan or sulphhydryl form ($-SH$). Neoarsphenamine is probably converted in the body into the arsenoxide form, $RAs=O$, and Voegtlin and his colleagues showed that the action of arsenoxide on trypanosomes, both in the test-tube and in the living rat, was inhibited by adding sulphhydryl compounds such as cysteine or glutathione. Later the same workers¹⁹ demonstrated that the toxic action of arsenoxide for the rat itself was inhibited by the intravenous injection of glutathione in the reduced form. The toxic action was also lessened by feeding rats on a mixture of glutaminic acid and cystine, which are the

constituents of glutathione. The conclusion from these observations is that when compounds containing sulphhydryl groups are administered, arsenic which is present in the body combines with these sulphhydryl groups rather than with the sulphhydryl groups of protoplasm.

These observations are probably related to the demonstration by Messinger and Hawkins²⁰ in 1940 that a meat diet is very effective in protecting dogs against the toxic action of arsenic on the liver, and that a fat diet, on the other hand, conduces to toxic effects. For example, one dog eating a high fat diet became toxic and inactive with a high icteric index after the injection of 0.04 g. per kg. arsphenamine. When a protein diet was substituted the icteric index fell and the dog became active. Three more arsphenamine injections were then given, but in spite of these the bilirubinaemia fell and the dog remained well. It was then put back on the fat diet, when the icteric index rose from 2 to 21 units without more arsphenamine. A protein diet has similarly been shown to protect the liver of a dog against chloroform, and it is the sulphur-containing amino-acids in the protein which give the protection²¹; it may be these amino-acids which protect against arsenic. It should be remembered that casein contains relatively much cystine.

A new approach has recently been made by Sandground and Hamilton,²² who were stimulated by the observation of Woods²³ that *p*-aminobenzoic acid inhibits the action of sulphonamides on bacteria. Sandground and Hamilton wondered whether *p*-aminobenzoic acid would inhibit the action of pentavalent arsenicals such as tryparsamide on trypanosomes. They looked for this action, failed to find it, but discovered that *p*-aminobenzoic acid greatly reduced the toxicity of large doses of tryparsamide, carbarsone, acetarsone, and other pentavalent arsenic compounds. For example, 1.5 g. per kg. carbarsone killed all rats; but if this dose was followed by oral administration of 0.75 g. per kg. *p*-aminobenzoic acid, repeated twice on successive days, all rats survived. Some protective action could be demonstrated with doses so low as 15 mg. per kg. The protection afforded by *p*-aminobenzoic acid was greatest when it was administered either together with carbarsone or one hour previously; the protection was less if *p*-aminobenzoic acid was given after the carbarsone. Similarly, *p*-aminobenzoic acid gave good protection against arsanic acid if it was given three hours before. Sandground considers that the protective action is due to *p*-aminobenzoic acid interfering with the reduction of the pentavalent arsenicals to the arsenoxide form, inasmuch as *p*-aminobenzoic acid has very little protective action against the trivalent arsenical compounds like neoarsphenamine, or against arsenoxides like mapharsen. Mapharsen, it is interesting to note, is rapidly replacing neoarsphenamine as an antisyphilitic remedy in the United States; probably more than half the cases in the U.S. Army are treated with mapharsen.

Still further work from another source has now been published. Goldstein, Stolman, and Goldfarb²⁴ state that

methyl chalcone of hesperidin reduces the toxicity of mapharsen for rabbits. These workers were concerned to find a remedy for the encephalopathy which has occurred in 1.3% of patients treated for syphilis with mapharsen by the rapid 5-day method. Goldstein and Stevenson observed that mapharsen in large doses damaged the brain capillaries of rabbits, and Goldfarb proposed the use of an aqueous extract of whole lemon to prevent arsenical encephalopathy. Lemon was believed to contain the factor diminishing capillary permeability known as vitamin P. Later a chalcone of hesperidin (a vegetable dye having vitamin P activity) was isolated from lemon peel, from which was prepared a methyl chalcone. Goldstein and his colleagues have now used this methyl chalcone in conjunction with mapharsen, and state that it gives some protection against the toxic effect of large doses of mapharsen. Mapharsen in doses of 8 mg. per kg. twice daily for 4 days killed 13 out of 30 rabbits. If, however, the methyl chalcone was given intravenously daily for 7 days before and for 4 days during the mapharsen injections, in doses of from 10 to 30 mg. per kg., then only 3 rabbits out of 30 died. These experiments are, however, still in the preliminary stage.

Of the three lines of work described, the first seems the one most likely to have a clinical application, though the second might also be tried. Both compounds, like cystein, containing sulphhydryl groups and *p*-aminobenzoic acid are fairly easy to obtain, and both might be tried as remedies for arsenical dermatitis or for arsenical jaundice. Let us hope that this is being done.

MEDICAL HISTORY OF THE WAR

Sir Arthur MacNalty's paper on the Official Medical History of the War,¹ like all his writings, is both scholarly in substance and literary in form. That he should be editor-in-chief of the projected History is one good omen of success in an undertaking all the prognostic signs of which are not equally encouraging. The scale of the plan is vast: the medical history of the last war, which was mainly a history of the R.A.M.C., ran to 12 volumes:

History of this war is to cover not only the three fighting Services but the medical civilian services as well. There are few human activities of medical interest in which a state of "total" war does not affect, the programme envisages a virtually complete medical history of the civilian population of Great Britain and Northern Ireland as well as of the fighting Services in all parts of the world through a period inevitably longer than 1914-18. This suggests a series of volumes in comparison with which the 12 volumes edited by Sir William Macpherson will seem curt. The youthful Macaulay said of a voluminous author: "Such a book might, before the deluge, have been considered as light reading by Hilpa and Shallum. But unhappily the life of man is now three-score years and ten; and we cannot but think it somewhat unfair in Dr. Nares to demand from us so large a portion of so short an existence." But nobody expects that any individual will read the whole series; the object is, presumably, to lighten the labours of specialists who must otherwise consult original documents, some of which will

be inaccessible and others destroyed. It might therefore be suggested that many items of the programme ought to be treated by the official writers rather in the spirit of guides than of formal historians. For instance, the history of civilian mortality rates during the war must be written by the expert staff of the General Register Office. Now, reasons of alleged security have restricted the literary output of the General Register Office; but, sooner or later, all the facts must be set out and commented on in the regular serial publications. No doubt a competent person could use this material to compile a volume of the History, but that would mean not only great repetition but a presentation of the facts out of the appropriate setting. A fascicule, rather than a solid volume, consisting of an annotated bibliography (including manuscripts as well as printed sources), would in our view be the appropriate method. This is probably true of other parts of the programme. It is easy to make the better enemy of the good. One recalls Mr. Casaubon of *Middlemarch*. We have no doubt at all that the editorial committee are as learned as and much more intelligent than George Eliot's character, but it is possible that by 1956 (the last volume of the medical history of 1914-18 appeared in 1931) interest in the details of the present war will have waned; it might even be that they did not seem to have much relevance to future wars. If so, general readers would only be attracted by the merit of the writing. The song is always of arms and the man. Let us at least hope that the editor-in-chief, or some colleague with a comparable literary gift, will write one volume which will convey a general impression. Experts have decided that J. F. Green's little book contained various errors and did not give a wholly correct account of forces and tendencies. Macaulay has been convicted of still graver faults. But most of us feel more grateful to Green and Macaulay than to the learned contributors to accurate but much longer and far duller works by specialists.

TRICRESYL PHOSPHATE POISONING

In a small popular handbook of to-day¹ there is a description of the "Plastic Man" in the future "Plastic Age" from his nursery full of bright unbreakable objects, through a dustless, rustless world, to his final hygienic enclosure in his inexpensive moulded coffin. Already the "plastics" and "plasticizers" used in modern industry are legion. They enter into the manufacture of such diverse articles as gun turrets and babies' rattles; machine housings and lipstick cases; aircraft dopes and microscope mounting materials. Their smooth clearness reveals no hint of danger to those who either make or use them. Yet the raw materials of many plastics are dissolved in solvents of known and unknown toxicity, and added to them are complex lubricants, or plasticizers, of similar potential capacity for injury. One such plasticizer—tricresyl phosphate—has recently been incriminated as both a system poison and an external irritant.

Tricresyl phosphate and the closely allied compound triphenyl phosphate belong to the chemical families known as the aliphatic and aromatic esters. They are of low volatility, and their function as plasticizers is that of increasing the stretch and decreasing the brittleness of plastic materials. One of the first intimations of the toxic action of tricresyl phosphate arose from its use as a denaturant in a cheap alcoholic extract of Jamaica ginger—the "jake beverage" of prohibition days. An outbreak of "griping paralysis" in Cincinnati in 1930 affected more than 200

¹ J. R.A.M.C., 1943, 81, 51.

² *Plastics*, by V. E. Yarsley and E. G. Couzens, Pelican Books, 1941.

people within six months. A similar outbreak in Durban in 1937 was traced to the use of cooking oil transported in drums which were believed to have been used for storing commercial plastics: the oil was found to contain 0.2 to 0.3% of tricresyl phosphate. Yet another source of poisoning by ingestion of tricresyl phosphate has been found in "apiol pills" containing 28 to 50%. In 1942 the occurrence of a few cases showing similar symptoms in workers employed in the manufacture of tricresyl phosphate led to an Order under Section 43 (3) of the Workmen's Compensation Act adding poisoning by tricresyl and triphenyl phosphate to the Schedule of Industrial Diseases.

The symptoms of systemic tricresyl phosphate poisoning closely resemble those of infantile paralysis, but are in fact due to severe polyneuritis with disability especially in the motor functions. An initial few days of gastro-intestinal disturbance, which represents the accumulation of a final paralyzing dose, is followed by a latent period of eight to twelve days, during which there is believed to develop a hyperplastic fibrosis of the smaller arteries and capillaries, and finally paresis, affecting first the calf muscles and later the intrinsic muscles of the hands. The gait has a typical "slapping" character, and there are numbness and tingling of the feet and hands. Recovery is slow. Often there is little change up to eighteen months, and residual paralysis after three years is not uncommon.

Even more recently suspicion has fallen on tricresyl phosphate as the causal agent in a form of dermatitis associated with the wearing of synthetic tortoiseshell spectacles. This takes the form of itching and serous discharge behind the ears, with slighter reactions over the bridge of the nose and at points of contact with the side-pieces. In similar cases reported by Berkhoff² in 1938 it was believed that the irritant was tricresyl phosphate used as a plasticizer in the synthetic tortoiseshell. Some amateur medical detective might perform a service to humanity by following the trail of the spectacle frames from patient to supplier, from supplier to manufacturer, back to the original plastic and plasticizer. The final tracing and enumeration of all articles made by this particular process might lead to the elucidation of many mysterious cases of sensitization dermatitis of unknown origin.

PATULIN AND THE COMMON COLD

The great therapeutic success of penicillin has led to the examination of hundreds of mould species for their capacity to produce similar antibacterial agents. A large number, particularly of the genera *Penicillium* and *Aspergillus*, have been found to produce such agents. But without exception they fall short of penicillin both in bacteriostatic power and in freedom from toxicity. They belong to two main classes: those which, like penicillin, act almost exclusively on Gram-positive bacteria, and those which act equally on Gram-positive and Gram-negative. H. Raistrick has identified a large number of these substances, and has chemically identified and even synthesized some of them. They are readily produced, since the yield from mould cultures is large and stable: these are advantages over penicillin which would facilitate therapeutic use should any such scope be found for their employment. It is such a mould product which is now acclaimed for a totally unexpected purpose—the cure of the common cold. The circumstances in which this discovery was made are strongly reminiscent of those which, originally led to the identification of penicillin itself, both involving a large element of chance which might have gone for nothing without the

vision and capacity to seize it. A supply of patulin, the antibacterial derivative of *Penicillium patulum* Bairier, had been sent to the laboratories of the Imperial Cancer Research Fund for therapeutic tests in cancer. We are not told the results of any such tests, but W. E. Gye was suffering from a severe cold when the material was received, and tried a solution of it as a nasal douche with marked relief. Some of his colleagues having confirmed this effect in their own persons, a large-scale clinical trial was carried out by W. A. Hopkins at a Naval establishment. Here sufferers from colds were treated either with a solution of patulin in phosphate buffer or with phosphate buffer solution alone, the subjects in no case knowing that any control material was being used, while in some experiments not even those in direct charge of the treatment knew which solutions were active and which not. It was found best to classify results simply into "cured within 48 hours" or "not cured": they varied somewhat during the three months covered by the study, but the mean figures for the whole period were 58% of recoveries in treated cases, and 9.4% in controls. These clinical observations, together with an account of patulin from the chemical point of view by Raistrick and his colleagues, and information about its other biological properties, have now been published (*Lancet*, Nov. 20, 1943, p. 625) in a symposium which has naturally produced loud echoes in the lay press.

The main impression which these disclosures produce is one of astonishment that a substance with these properties should have any such action. Patulin is toxic: 0.5 mg./20 g. intravenously kills 65% of mice, and a concentration of 1 in 2,000 inhibits phagocytosis. The concentrations inhibiting the growth of various bacteria, Gram-negative as well as Gram-positive, are mostly between 1 in 33,000 and 1 in 100,000. The concentrations recommended for therapeutic use are 1 in 5,000 or 1 in 10,000. It is true that this strength leaves a favourable margin from both points of view—toxicity and bacteriostasis—but it is a very narrow margin. It has also to be remembered that the majority of colds are believed to be due to a virus, and that there is no evidence whatever that any mould product has an inhibitory action on the growth of viruses. That the effect on the cold is directly antimicrobial is therefore perhaps improbable; it is certainly unproved. A merely vasoconstrictor or antisecretory effect seems unlikely in view of its duration: six hours of complete relief from symptoms is a common experience after one application, and four-hourly repetition is all that has been found necessary. Nevertheless patulin clearly calls for investigation from the purely pharmacological point of view. What other type of action it may have is simply an interesting field for sheer speculation. While welcoming what is evidently a great advance, offering the prospect at least of some relief from discomfort on an enormous scale, we would suggest that, besides the further clinical trials envisaged, serious attempts should be set on foot to elucidate the process involved. With better understanding it may prove to have even wider implications.

The authorities of the Royal Infirmary, Worcester, have set up a Hastings Memorial to mark the bicentenary of the hospital. The Council of the B.M.A. at its meeting on July 28 recorded its high appreciation of the proposal. The memorial takes the form of an overmantel in oak for the board room in which are incorporated the existing portrait of Sir Charles Hastings and the reproduction of his address delivered to the first meeting of the Provincial Medical and Surgical Association, which became the British Medical Association in 1856.

² *Arch. Derm. Syph.*, 1938, 33, 746.

RESPIRATORY TUBERCULOSIS

EFFECT OF THE WAR ON THE LENGTH OF THE INTERVAL BETWEEN NOTIFICATION AND DEATH

BY

E. LEWIS-FANING, B.Sc.Econ., Ph.D.

Of the Statistical Staff of the Medical Research Council

Among many factors that have been suggested as influencing the increase in tuberculosis mortality which accompanied the outbreak of the war is that of lowered resistance to the disease by those already infected. It is argued that if resistance were lowered to the point at which the average duration of the disease was shortened, this would tend to produce the higher mortality rates that were a feature of the 1940 and 1941 statistics.

Method of Investigation

The medical service of the Middlesex County Council, realizing the desirability of answering this question, offered for statistical analysis their records of fatal cases terminating in the years 1937 to 1941. The method of approach to the problem has been to compare the interval between notification

Analysis of the deaths in the pre-war period shows that the missing data were not distributed by age in the same proportions as the deaths officially recorded. According to official figures, 43% of the male deaths were at ages over 45, yet 72% of the male leakage occurred at these ages. Again, 20% of the recorded female deaths were at ages above 45, yet the female leakage was 41% in the same group.

Returns were submitted by each of the seven chest clinic or dispensary areas into which, during the period under review, the county was divided for the purpose of administering the tuberculosis service. The information supplied in each fatal case was: Sex, age at death, date first seen by the tuberculosis officer, whether diagnosis was of pulmonary tuberculosis or tuberculosis of other organs, and date of death. The analysis was restricted to deaths due to pulmonary tuberculosis, since there was not sufficient material from which to make satisfactory deductions in regard to the other forms. Two dispensaries supplied the date of notification instead of the date first seen; but exhaustive comparisons between the results given by these two areas as compared with the remainder showed no differences which could be ascribed to the distinction made.

The data were carded and the durations calculated to the nearest month. The frequency distributions in broad duration

* Duration is defined throughout this paper as the period elapsing between notification (registration as a tuberculous person) and death.

and death for two periods in which death occurred: (1) the pre-war years 1937-9, and (2) the war years 1940 and 1941. Shorter average duration should appear in the second period if the postulate of the preceding paragraph is correct. The term "duration of disease" as used in this analysis is defined as the time elapsing between notification (or registration as an infected person) and death.

The data are not complete; only about 75% of the deaths recorded in the County of Middlesex by the Registrar-General during these five years appear to have come under the county council's scheme for the treatment of tuberculosis.* Of the remainder a number of persons escape notification as suffering from tuberculosis until after death; and a further proportion, who were notified, were treated privately and not under the county service. It can be shown that the proportion who escaped the net was constant in both periods, and hence the comparison is not invalidated even though the accuracy of the figures as measures of the absolute duration of the disease is somewhat reduced.

groupings, in both absolute and percentage form and distinguishing age and sex, are shown in Table 1; also the percentage age distribution at death of these fatal cases.

Findings

Age Distribution.—Statistical tests showed no significant difference between the age distributions in the two periods.

Duration Distribution (All Ages).—Considering first all ages combined, Table I shows that in the three years 1937 to 1939 1,271 deaths of males occurred from pulmonary tuberculosis among patients under observation by the Middlesex Tuberculosis Service, as against 944 in the two-year period 1940-1. In the pre-war period the duration was of less than one year in 43% of the deaths, as compared with 42% in the war period. Those with durations of more than one year but less than five years accounted for 44% in the pre-war and 41% in the war years; while there were 13% in the pre-war and 17% in the war years with durations ranging from five to twenty-six years. Similarly for females, 41% of the 930 deaths in 1937-9 and 46% of the 666 deaths in 1940-1 were of less than one year's duration; 46% as against 41% were of more than one but less than five years; and 13% in both periods.

* A similar test could be applied by all tuberculosis centres to furnish a rough guide as to the extent to which tuberculosis cases in any administrative area were seen by the official medical service.

recorded durations of more than five years. For neither sex were the distributions in the two periods different in the statistical sense; or, in other words, the changes which occurred in the percentages were not greater than one would expect to arise merely by chance.

Durations within the Age Groups.—Statistical tests* applied to the frequency distributions of the durations within the age groups showed that only at ages 45–54 for males and at ages 45 and upwards for females were they really dissimilar in the two periods. In both cases the proportion of patients with a duration of over five years increased in 1940–1. Certain features of the table were suggestive, but when tested statistically were found to be inconclusive.† These were: (a) an increase in 1940–1 in the proportion of male deaths with durations longer than five years, the amount of increase being small but persisting at every age group; and (b) a similar small but consistent increase in the proportion of female patients with durations of less than one year, accompanied by a decrease, except at ages under 25, in the proportion with durations of one to five years.

One other point is perhaps noteworthy even though it is hardly relevant to the present problem. The proportion of cases in which death occurred less than a year after notification showed for males the same relationship with age in both periods—namely, that it was lowest at age group 25–34 and thereafter increased with age. This was also true of the female patients

greater than could arise by chance. Neither instance is, however, evidence that average duration decreased with the outbreak of war, but suggests the contrary. Four significant differences occurred among the 12 pairs of means for the females, and they all arose in the duration group in which death occurred within one year after notification. But while three showed the average duration in 1940–1 to be less than in 1937–9, the fourth recorded an increase, and statistical tests indicated that no definite deductions could be drawn from these results.

Conclusions

The analysis has produced no conclusive evidence of any appreciable decrease in the average length of time between notification and death from pulmonary tuberculosis in the two years following the outbreak of war. Nor do the results, presented in three groups according to whether death occurred within one, five, or more years after notification, show the existence of any movement to indicate that during the war years a higher proportion of the deaths occurred at a relatively shorter interval after notification.

There is perhaps a suggestion, which statistically is unproved, that among female patients in the more acute group—those dying within a year of notification—the average duration was a few weeks less in 1940–1 than in 1937–9.

The conclusion must be, therefore, that there is no evidence, from the experience of the tuberculosis service of the County

* = Significant difference.

in the more recent period, but in 1937–9 the smallest proportion occurred in age group 35–44.

Average Length of Duration.—A comparison between the pre-war and war years as regards average length of duration, in age groups, is shown in Table II. Separate indices are given for the duration groups used in Table I, since the mean for all durations combined appeared to be unduly influenced by a few long-drawn-out cases. The difference between each pair of means was tested for statistical significance, and the table shows the ratio of each difference to its standard error—15 values for males and 12 for females. Of the former, in only two instances was the ratio greater than 2, and only in those two instances could it be concluded that the difference was

of Middlesex, of a lowered resistance to the disease to the point at which duration was shortened, and hence no evidence that lowered resistance was a causative factor in the increase of tuberculous mortality which occurred in 1940–1.

My acknowledgments are due to the staff of the Middlesex County Medical Service for the assistance they have given in connexion with the preparation of this paper.

Reports of Societies

CANCER AND THE YOUNG GYNAECOLOGIST

In his presidential address to the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on Oct. 15 Dr. MALCOLM DONALDSON addressed himself to the subject of malignant disease, more particularly from the standpoint of the younger generation of gynaecologists. He reminded them that cancer was a research subject calling for team work. In order to take his or her place in the team the young gynaecologist not only must be good in this special branch of practice and an expert surgeon but must have a considerable knowledge of radiotherapy, and be able to take an intelligent interest in advances in the histology, pathology, and aetiology of the disease.

After pointing out that all treatment of cancer, whether for private or hospital patients, should be carried out in a well-equipped and properly staffed institution, Dr. Donaldson dwelt upon the importance of early diagnosis and the value of educational lectures to the laity. Again and again it was said, "If only this patient had sought medical advice earlier we should have had a chance," but very little had been done to remedy this state of affairs. It was complained that the lectures organized by the British Empire Cancer Campaign were likely to turn people into neurasthenics; he was convinced that the exact opposite was true. As soon as people began to talk freely about cancer in the same way as they talked about other diseases it would be possible to do away with the fear and ignorance which were so largely responsible for the late diagnosis of cancer even in accessible sites. Unfortunately, even when early diagnosis was obtained, the good was often nullified by the fact that the patient's name was put on a waiting list, and, if the gynaecologist was not interested in cancer, the name would remain on the list for weeks before the patient was admitted. Cancer should be regarded as an acute disease, and waiting lists as a blot on civilization.

Dr. Donaldson went on to discuss the difficulties of treatment, in particular the assessment of the effect that treatment had on a growth. He drew attention to the criterion suggested by Spear and Glücksmann which would make it possible within a few weeks of the start of treatment to assess the effect on the primary growth. This method consisted in counting the entire cell population of an area of tissue taken from the growing edge of the growth before and after irradiation, and then determining the number of cells in each of four categories—namely, dividing, degenerating, resting, and differentiating cells. By plotting the results as percentages against time on a graph, it had been found that the curves showed certain characteristics by which the effectiveness of the irradiation could be judged.

The manner in which radiotherapy brought about certain results had been studied for many years. At one time it was thought that radium or x rays acted as a kind of cautery—"a red-hot poker," as one surgeon expressed it—but it was soon realized that cancer and other quickly growing tissues were more sensitive to radiotherapy than normal ones. The outstanding fact was that large growths were usually more difficult to eradicate than smaller ones, in spite of the fact that each individual cell in both classes of tumour received the same amount of irradiation; thus an indirect action was suggested, and this indirect action, in his view, was the more important factor. The young gynaecologist must search for an optimum dose of irradiation which would encourage differentiation. Possibly a large dose might have the opposite effect.

Treatment by radiotherapy had improved during the last few years, but some practitioners still used radium or radon with very little knowledge of the subject. The bad results of treatment, so often due to ignorance; did not appear at once, and mistakes in technique were therefore not so obvious to the practitioner as bad surgery would be.

The Cancer Act

After stressing the need for more research work on the subject of pain in advanced cases of cancer, Dr. Donaldson spoke finally of the future organization in which the young

gynaecologist was likely to play his or her part. He believed that the Cancer Act of 1939 would prove to be one of the very greatest benefits in helping to solve the cancer problem. The Act itself was short and rather unimpressive, but everything would depend on the way it was carried out. It compelled certain of the local authorities to submit schemes to the Ministry of Health which would provide efficient diagnosis and treatment for cancer patients within their areas. It did not require each local authority to have a separate scheme; on the contrary, powers were provided to compel the setting up of joint schemes where these were desirable. The Act also compelled local authorities to consult with the voluntary hospitals and other medical bodies within their boundary. Most of the treatment of cancer had been, and was being carried out in the voluntary hospitals, the Act provided a golden opportunity for the voluntary hospitals to get together and draw up schemes which would also embrace municipal hospitals and their services, and provide a first-class cancer organization. He believed that any large hospital which decided to adopt an isolationist policy would eventually lose all its cancer patients. Such schemes would provide for diagnostic and consultative centres, treatment after consultation between surgeon and radiotherapist, efficient follow-up departments, statistical departments, educational lectures to the public, and a number of other services in connexion with cancer. In a word, they would offer far more efficient routine treatment than was obtained at present by most patients, and an ever-increasing opportunity for planned research.

EPIDEMIOLOGY OF POLIOMYELITIS

At a meeting of the Section of Neurology of the Royal Society of Medicine on Oct. 21, with Brig. HUGH CAIRNS in the chair, the subject for discussion was the present position with regard to the epidemiology of poliomyelitis.

Prof. S. P. BEDSON said that up to a few years ago it was accepted that the primary focus of infection of poliomyelitis was in the nasopharynx. The virus of poliomyelitis was confirmed neurotropic—that was to say, it developed only in nerve cells. It was found in the central nervous system, the nasopharynx, in the stools, and nowhere else. Of the less artificial means of producing infection in the monkey the application of the virus to the olfactory mucosa was most likely to succeed. It had also been found that if the olfactory mucosa had been prepared by chemical treatment such as zinc sulphate, then the monkey became insusceptible to infection by the nasal route. No one to-day contested the accuracy of those observations, and it had to be admitted that the conclusions drawn from them were neither unreasonable nor illogical. Even the occasional spread of poliomyelitis by milk for which there was some evidence, was not out of keeping with the conception of this disease being spread by infective droplets, since in a condition like scarlet fever, which was droplet-spread disease, milk-borne outbreaks occurred. One feature of the epidemiology of poliomyelitis which did not fit in with this conception was the seasonal incidence. Poliomyelitis was a disease of late summer and early autumn, unlike droplet-spread infections, which were diseases of winter and early spring. In support of the alimentary tract hypothesis some experimental evidence that the monkey could be infected by injecting the virus into the intestinal submucosa, though some critics had held that the method was too artificial, gave indications of value in the aetiology of the natural occurring disease. Further work in recent years, however, had gone far to establish the view that infection entered by the alimentary tract. In the Toronto epidemic of 1937 a 1 per cent sulphate spray was given a thorough trial and was found to have no preventive value. Recent studies in America had shown that, with an adequate technique, the virus of poliomyelitis could be demonstrated in the stools in human cases with remarkable regularity. Moreover, the virus had been isolated from the sewage in communities in which poliomyelitis was epidemic. Five out of 19 specimens collected from sewage in the neighbourhood of hospitals where poliomyelitis cases were being nursed showed positive results. Samples collected beyond a certain distance from the hospital or after the epidemic had ceased, or samples examined more than 24 hours after collection, gave negative results, suggesting that the vir

destroyed fairly rapidly. The recognition of the importance of the alimentary tract as a portal of entry of infection necessitated a recasting of views on the epidemiology and on control measures.

Poliomyelitis in Malta

Prof. H. J. SEDDON gave a description of the poliomyelitis outbreak in Malta during the bombing and siege of the island. The people of Malta during this period had lived in cellars and rock tunnels under very overcrowded conditions in a state of poor nutrition; but the epidemic spread to the neighbouring island of Gozo, where there was no bombing and where there was plenty of food. The epidemic, which started just after the relief of Malta, affected about 400 children and about 60 men in the Services. The children affected were mostly in the 0-5 age group (368 cases); in the 6-10 age group there were only 23 cases, and in higher age groups it was negligible. The Services epidemic affected only British and Dominion troops; none of the Maltese troops were affected, and the epidemic began rather later than the Italian one.

The outbreak threw a great strain upon the hospitals; another difficulty was the fatalistic attitude of the parents, who would not bring their children up for examination, so that it was necessary to tour the island and examine the children in their own homes, which were often no more than holes in the rock. In these circumstances accurate muscle-charting was not possible. Through the co-operation of the Royal Air Force some dried duralumin was obtained, also some spongy rubber salvaged from German aircraft, and in that way a sufficiency of splints was provided. A severe outbreak of scabies complicated the picture, and it often took a long time to get the children clean enough for ordinary massage. About one-third of the children made a good recovery within four months. The incidence of serious crippling was between 25 and 33%. There were 27 cases of abdominal paralysis, and a 10% incidence of facial palsy. Unless the children were watched very carefully they were liable to develop scoliosis. The mortality due to poliomyelitis alone among the children was 3.52%, and due to poliomyelitis associated with other conditions 2.77%.

As for epidemiological factors, the epidemic occurred at a time when the worst of the overcrowding was past. Overcrowding did not appear to be a serious factor in causation. The families in which the cases arose were investigated from the point of view of overcrowding. In some cases there might be seven or even ten people together in one room at night, but the number of poliomyelitis cases occurring in these overcrowded families was quite small—almost invariably only one child per family. Sometimes three, four, or more persons had slept in the same bed as the patient. Therefore the overcrowding factor could not have been very important; otherwise there would have been a pandemic. It was also difficult to assess the factor of poverty. Fourteen of the families in the outbreak were in comfortable circumstances. The civilians, if they were lucky, were receiving 1,500 calories a day; the men in the Services, 2,300 calories. The incidence among the civilians was 1.48 per thousand of population, and the incidence among the men in the Services almost exactly the same, while the incidence on the island of Gozo, where there was plenty of food, the incidence was 1.31. Nutrition, so far as could be estimated, did not play an important part in the incidence of the disease. During the first three months of life there seemed to be passive immunity conferred by the mother; there was a higher incidence at six months, a still higher incidence at nine months, slight decrease at twelve months, a lower incidence in the second year, and a progressive diminution down to the age of 5, after which there were practically no cases at all. The youngest child in the family was most frequently affected, and the second youngest came next.

In the course of the discussion Prof. Seddon's remarks were supplemented by Dr. T. AGUS-FERRANTI, who said that the most constant clinical feature found in the histories of these affected children was periodic flushing. He was impressed by the number of mothers who told him that the children were flushed at one time and at another were deadly pale. Rigidity of the spine, which in the textbooks was said to be a common feature, was not observed. One of the most frequent complaints was of abdominal colic associated with uneasy micturition.

Correspondence

Sergei Sergevitch Yudin

SIR.—The publication of Prof. Sergei Yudin's paper in your issue of Nov. 6 prompts me to write a few lines about this dynamic personality. I trust that the fact that this communication on the treatment of gunshot fractures of the femur comes from the pen of a general surgeon will not induce my good friends who are masters of the orthopaedic art to pass on with averted eye, since Yudin's experience with fractures produced by enemy missiles is really immense. Until I recently made contact with him in Moscow I had in fact regarded this great surgeon as one whose special interest lay in gastric surgery; the orbit of his surgical activities is, however, wide and most catholic in its range. In peacetime he is served by 18 assistants in his great emergency hospital.

During the period of 14 years that he has been head of the Surgical Service of the Sklifassovski Hospital he and his assistants have extracted almost 5,500 foreign bodies from the oesophagus and bronchi with a mortality of just over 1%. Yudin had completed three months ago 89 operations of oesophagoplasty for severe simple stricture of the gullet; he and his assistants have performed nearly 5,500 operations on the stomach; there have been 100 operations of total gastrectomy for cancer with a mortality of only 30%. He has performed three hind-quarter amputations for sarcoma of the hip or upper femur; he has completed a number of plastic operations for congenital absence or atresia of the vagina, employing a segment of the intestinal tract for the purpose. The ulcers of the stomach and duodenum which the recent Anglo-American-Canadian Mission saw operated upon in this hospital possessed the most fearsome dimensions and an almost prohibitive fixity, yet resection was successfully carried out. The organization of "femur brigades," to which allusion is made in the article in your *Journal*, is due to him, and dates from the time that he became one of the consulting surgeons to the Red Army. The stupendous character and magnitude of the surgical work for which Yudin has been responsible are all the more wonderful when it is remembered that a gunshot wound of the spine in the last war confined him to bed for 9 months with paraplegia. An illness in the beginning of 1942 again restricted his activities, and his fervent patriotism chafed at his inability for a time to serve with the famous Red Army. Fortunately for the Russian wounded his health and his indomitable spirit and energy have been restored. The Royal College of Surgeons of England and the American College of Surgeons conferred an Honorary Fellowship upon this master-surgeon in Moscow; he is indubitably one of the greatest surgeons in the world to-day.—I am, etc.,

London, W.1

GORDON GORDON-TAYLOR.

Spinal Anaesthesia

SIR.—I feel attention should be drawn to the possible results which may attend the use of the spinal solution mentioned in Prof. Yudin's article on gunshot fractures of the limbs in your issue of Nov. 6. He advocates 1 c.cm. of 1% nupercaine (Russian synonym: sovkaïn). For spinal anaesthesia the strongest concentration of this drug available in this country is 1/2% (1:200). 1 c.cm. of this concentration produces anaesthesia of the lower limbs. If more extensive anaesthesia is needed I would prefer to increase the volume rather than the concentration until I have further proof that a 1% solution of this potent anaesthetic does not carry with it the possibility of permanent damage to nerve roots.—I am, etc.,

Oxford.

WILLIAM W. MUSHIN.

Anxiety and Hysteria

SIR.—In their admirable paper on "Anxiety States in the Navy" (Nov. 13, p. 603) the authors say: "We attach great importance to the necessity for regarding hysterical manifestations as but symptoms of the fundamental anxiety, and no attempt has been made to separate those cases which showed hysterical phenomena from the general mass of anxiety states." This is a welcome change from the statistical evaluations of

anxiety and hysteria which have poured out since the war—and before. These have always appeared to me somewhat light-hearted, if not entirely worthless, because they are compiled on the assumption that all psychoneurotics are either anxiety cases or hysterics. In point of fact the largest class is that of the anxiety-hysterics. These are the cases which predominate both in peace and in war because partially transferred anxiety is commoner than either pure anxiety or pure hysteria.

I submit, therefore, that we are obliged to adopt an elastic conception of the psychoneuroses rather than any rigid classification based upon psychopathological dogma. This is all the more necessary in that the evaluation of psychoneurotic symptoms is bound to be to some extent subjective. I submit, therefore, the following four points:

1. The pure anxiety case is devoid of dramatization and is relatively rare.
2. The pure hysteric dramatizes all her anxiety in its nascent state. She is also rare.
3. The predominant group is rightly described as anxiety-hysteria in that the anxiety is partially dramatized.
4. The symptomatology of the psychoneuroses partakes therefore of the nature of a spectrum, and any classification in terms of pure cases tends to be confusing.

And if we take this view we may get a clue to the question that Sir H. H. Bashford puts in his letter (p. 619). If peptic ulcer is closely associated with pure anxiety it follows that it is least likely to occur in hysterical patients. The ratio of pure hysteria in women as opposed to men may not be capable of objective demonstration, but we can at least say that it is much commoner. Hence we may reasonably infer that women escape a measure of peptic ulcer on account of their greater facility for transforming anxiety into hysterical manifestations.—I am, etc.,

London, W.1.

H. CRICHTON-MILLER.

Mind and Stomach

SIR.—If peptic ulceration is a psychosomatic disorder, perhaps an explanation of the different incidence in the sexes mentioned by Sir Henry Bashford in his letter is to be found in the different psychological outlook of men and women. For long ages the "weaker" sex has been regarded as especially liable to nervous upsets. Hysteria, as the name implies, was thought to be a disease peculiar to women. The "going into a decline" so common last century was probably always a feminine reaction to emotional mishaps. A nervous breakdown would be the current description. Nervous debility is most sympathetically regarded if it occurs at the menopause or, in a woman, as the result of war strain. The position for the man is different. He has an equally old tradition behind him, but in his case it is not softness but toughness that is expected. Nervous debility does not sound too good for him. Unconsciously—that is to say, unaware, and unable to control it if he were—he is driven to the somatic moiety of the mind-matter medal. A duodenal ulcer confirmed by x rays, and particularly if it has bled or burst, will solve many environmental difficulties, and with a minimum or no loss of face. Maybe the full emancipation of women, among other changes, will lead to a general levelling out and the disappearance of some of these sex differences.—I am, etc.,

London, S.W.1.

E. GALLOP.

SIR.—Sir Henry Bashford (Nov. 13, p. 619) says: "The national and international environment during the last twenty-five years has been the same for both sexes, and it would be difficult to argue that women are less exposed to the ordinary stresses and strains of everyday life than men. If there is a strong psychological factor at work in the causation of peptic ulceration, why are women so relatively immune?"

But are "ordinary stresses and strains" by themselves often causes of illness? It is true that Davies and Wilson (*Lancet*, 1937, 2, 1531) found that "events" preceded peptic ulceration in 84% of a series of 205 patients. These events were of three main classes—changes of work, financial difficulties, or illness or death of a member of the family. But they also found that 78% of the same series of patients had an unusual mental tension. Wilson (*Brit. J. med. Psychol.*, 1939, 18, 112) described the main basis of this mental tension in a series of 50 patients who had had haematemesis as a need for dependence, often

driven by fear into an aggressive and exaggerated independence. Surely the usual early upbringing of boys, with its emphasis on the suppression of emotions of dependence in the idea of "manliness," is a more likely source of this form of tension than that of girls, who are allowed to keep much their dependence and to express more freely the emotion natural at that age.

Whether or not this may be a reason for the relatively greater incidence of peptic ulceration in males than females there is no doubt that problems of adjustment to personal relations during the first five years of life differ greatly between the sexes.

The main question raised by Sir Henry's letter is whether when we acknowledge (as is now so common) the "psychic," "nervous," or "anxiety" factor in this or that disease we mean mere worry on the conscious level or morbid and precipitated perhaps by conscious worry, but exaggerated reaction by reason of an abnormal state of tension rooted in the unconscious mind.—I am, etc.,

Aylesford, Kent.

E. P. EDMOND.

Functional Dyspepsia

SIR.—Sir Henry Tidy (Oct. 16, p. 473) arrives at the conclusion that "men suffering from non-organic dyspepsia in many cases make useful soldiers providing they are detained too long in hospital. Cure of symptoms should be attempted. An excess of medical attention and investigation in exaggeration of symptoms and repeated admission to hospital." He gives as evidence for this statement the returns of diagnoses of Army personnel on discharge from Army for a given period in 1941. These figures show 0.03% of men were discharged from the Army under heading of "Non-ulcer Dyspepsia" and 42% were discharged from hospital with the same designation. He repeatedly emphasizes the bad effects of treatment upon this group, and points out that wide experience shows how easily they relapse on return to duty.

He indicates that a certain number of these men are fit to be useless in their units, and consequently are discharged from Army with the label of psychoneurosis. Unfortunately he does not give figures, which, if available, would be of considerable support to his thesis. Are "follow-up" figures available for non-ulcer dyspeptics discharged from hospital? He finds some interesting similarities between non-ulcer and ulcer dyspepsia. Approximately the same percentage have a history of similar symptoms in civil life. The sex ratio is also maintained, although the preponderance of males is greater in the ulcer group. Surely there is need for much further observation and investigation, possibly better conducted in the unit than in hospital.

In his 19% of patients with peptic ulcers whose symptoms began in the Army the average length of history was 18 months. This does not indicate that medical officers referred cases for special investigation without good cause. It is most unlikely that unit treatment of the non-ulcer group is materially different from those with ulcers. Better reasons for the earlier reference of dyspeptics to hospital in military life opposed to civil life are given in this paper.

Finally, what are the distinguishing features of a functional dyspepsia "organic in the sense of disturbance of function but not a psychoneurosis, in which there is an absence of recognizable anatomical changes or demonstrable disease in the stomach and duodenum and elsewhere in the body"? Any of the cases which have been produced by an excessive therapeutic zeal belong to this group?—I am, etc.,

A. S. THORLEY,
Major, R.A.M.C.

No. 2 Army Selection Centre.

"Duodenitis"

SIR.—In his authoritative article on peptic ulcer and dyspepsia in the Army (Oct. 16, p. 473) Sir Henry Tidy expresses concern over the term "duodenitis," but I am afraid that his proposal is too late and that the expression, however unsuitable, must come to stay unless someone supplies quickly a more appropriate word. I have been hoping that someone would come forward with a satisfactory definition. I do not feel able to do this myself, but on the occasions when I have employed the term, always, I hope, in inverted commas, I have intended

g: "I have spent a humiliating and profitless examination of this patient's duodenum; at the first examination complete pyloric spasm, which could not be overcome by alteration of position or pressure. On re-examination 30 minutes later, the stomach was nearly empty, overcoming the reluctance of the patient, a second examination. At irregular and infrequent intervals barium spurt rapidly through a contracted cap, but I do not at the deformity shown was constant, and on rare occasions I saw the cap dilate apparently at each time I was taken by surprise. Pressure causes discomfort. I have taken numerous films in various positions; none of them shows any barium in the duodenum. I have a compression device with quick change from fluoroscopy to radiography, but that shows no filling of the duodenum: I cannot pass the duodenal cap as behaving as if it showed a normal silhouette, for what on a few fleeting occasions, but I cannot show evidence of ulceration." This is an exhausting performance if it happens two or three times during a day, and at the end of it to be able to make use of a medical term such as "duodenitis"; but surely, in producing the telling phrase, we, or even more colleagues, could introduce something more.

The radiological investigation of the duodenum, with its difficulties in providing satisfactory evidence, is noted by our colleagues, and I regard this as a thick-set muscular male as one of the least satisfactory enterprises in ordinary radiological etc.,

CHARLES WROTH.

"Atypical Pneumonia" or "Pneumonitis"?

1. "Primary atypical pneumonia," which I have designated "P.A.P.," is being increasingly employed as the common condition of benign inflammation of the lung. This disease has been well known to clinicians for more than ten years, but it has not been generally recognized. It seems possible that it should come to be accepted as the official designation and for this reason it is desirable to consider appropriate to fulfil this purpose. "Primary" taken in conjunction with "pneumonia" supplied, for clinical experience shows that there is a general one or it originates in the upper part of the consolidation in the lung is merely an extension of this same condition has been described as "atypical" or "febricula," and the frequency of its use has only been recognized since the wholesale use of the word. Often there are no abnormal physical signs or at the most the signs of bronchitis. The condition "atypical"? In this context the word that the disease is closely allied to lobar pneumonia is far from the truth, for the two conditions are distinguished at a glance; the respiration rate is greatly increased, whereas in "P.A.P." it is normal. In fact the disease shows a clear-cut clinical entity. It is possible that a similar condition from a variety of infections, both bacterial and viral, may be that more than one cause will be responsible for this syndrome. There is an investigation into the results of chemoprophylaxis of cases; it seems clear that most cases are due to sulphapyridine, but it is possible that it does.

"Pneumonia" conveys the idea, both to the public, of a serious disease which has a high mortality if left untreated. The use of this word is therefore a misnomer. The use of this word is therefore a misnomer. The use of this word is therefore a misnomer.

entity concisely and appropriately. It is possible that increasing knowledge of the cause of the condition may eventually suggest a better term, but this is a matter for the future to decide.—I am, etc.,

London, W.1.

JAMES MAXWELL.

Vitamin B Deficiency

SIR,—We take the opportunity of replying to Dr. G. H. H. Benham, who criticizes our article on vitamin B deficiency (*Journal*, Oct. 23, p. 503) in your issue of Nov. 13 (p. 619).

1. Dr. Benham complains that in our italicized list of symptoms common to psychoneurosis and vitamin B deficiency we specifically omit diarrhoea, which to him seems inexplicable, because "diarrhoea is such a cardinal feature of the disease [pellagra] and so important in diagnosis." May we point out that it is not diarrhoea but constipation which is described as a constant manifestation of a moderate deficiency of the vitamin B complex and of vitamin B₁₂? Dr. Benham is doubtless confusing the symptoms of mild vitamin B deficiency with those of frank pellagra, which is rarely seen in this country. Although the general symptoms of pellagra are summarized in the textbooks by the three D's—diarrhoea, dermatitis, and dementia—these may be absent in the early stages. Diarrhoea is by no means a cardinal feature of the disease in its mild form. On the contrary, the presenting complaints of the potential pellagrin are often constipation, anorexia, dyspepsia, and a sore mouth and tongue—the *pellagra sine pellagra* of former writers.¹ It is important to emphasize that constipation may be present in the early stages of pellagra and that diarrhoea is only diagnostic in the late and advanced stages, which are rarely seen in Britain. Often diarrhoea and constipation alternate. To wait for the three D's is to delay diagnosis. A recent survey² of children in several pellagra families in the United States revealed that constipation was a common symptom.

Dr. Benham also calls us to task for omitting the condition of the bowels of our patients. Constipation and diarrhoea are such relative terms and used so loosely by hospital patients that little reliance can be placed on their statements in this respect unless the conditions are gross. Thus many a patient thinks he is constipated if he does not evacuate daily. It is only when stools can be inspected that the terms constipation and diarrhoea are worth noting.

2. We agree with Dr. Benham that other factors besides a marginal diet may precipitate deficiency disease. In fact we have stated that some of our patients suffered from lack of appetite and nervous dyspepsia, which would reduce further the intake and absorption of vitamins. Dr. Benham asks why one patient develops pellagra while another on the same diet does not. Such individuals are on a marginal diet, just above that supplying the minimal requirements of certain vitamins sufficient to prevent deficiency disease. A condition may occur in one patient and not in another, calling for an increased requirement of one or more vitamins (e.g., infection, hyperthyroidism, pregnancy, increased physical exertion); or resulting in diminished intake or absorption (e.g., gastro-intestinal disease, diarrhoea, anorexia); or interfering with utilization (e.g., liver disease, alcoholism); or increasing excretion (diuresis, pregnancy). One or more of these factors just tips the balance in favour of avitaminosis and deficiency disease. It is well known that many Chinese women appear normal in early pregnancy, but are often in *extremis* at the end from deficiency disease.³ According to modern conceptions, malaria, ankylostomiasis, chronic bacillary and amoebic dysentery, and intestinal tuberculosis are predisposing factors in tropical pellagra.⁴ Beriberi certainly seems more prevalent in malarial districts.⁵ Fox⁶ also points out that African natives do not develop scurvy on a diet low in vitamin C in the absence of precipitating factors (e.g., infection).

3. Dr. Benham states that psychopathologically there is no distinction between psychoneurotic patients and those we have described. He postulates early organic cerebral changes in both. Has he incontrovertible histopathological evidence that such changes do occur, or is this just inference from studies made on the brains of patients with chronic dementia? We know of no reported case of mild vitamin B deficiency (we exclude fatal pellagra) in which histopathological changes in the brain

have been demonstrated. Our primary concern was not with the histopathology of vitamin B deficiency but with the recognition of its oral and mental manifestations as an aid to early diagnosis. Patients suffering from this condition need never reach a hospital for nervous diseases—sometimes it is a mental hospital—if it is recognized and treated early enough, not by sedatives or psychotherapy but by diet and appropriate vitamin therapy.—We are, etc.,

Congenital Jaundice in a Man aged 77

SIR,—I have just seen a man who has been more or less strikingly jaundiced all his life and who was 77 years of age on Nov. 25. He enjoys good health, has hardly ever required medical aid of any kind, and continues at work—helping a married son with whose family he lives. I first examined him (in connexion with a life assurance question) in 1917, and from time to time have demonstrated his case at the Royal Society of Medicine (*Proceedings*, Clinical Section, 1917, 10, 13; 1928, 21, 3; 1938, 31, 39). He has scars from leg ulcers (1910), considerable deafness (old otosclerosis), and slight nystagmus. The blood bilirubin has, of course, been found in excess in the blood serum (negative direct Himmans van den Bergh reaction), but the urine has always been found free from bilirubin and from excess of urobilin and urobilinogen. There has never been any anaemia or enlargement of spleen or liver. No abnormal fragility of the erythrocytes (towards graduated sodium chloride solutions) has been discovered. The size and shape of the erythrocytes have never been sufficiently studied to enable one to exclude excess of spherocytes. Anyhow, the case seems to be a very unusual one of congenital haemolytic (acholuric) jaundice, arising doubtless from a germ cell mutation—possibly a new one, as there is no other example of jaundice in the family. The jaundice has not been transmitted to any one of his four children.

I am anxious to ascertain whether medical readers know of a case similar in all respects. I might mention that in the haemolytic (acholuric) family, which I recorded with G. Dörner (*Lancet*, 1910, 1, 227), the first ancestor known to have been affected was a man who had been "yellow all his life," and died at 76 (wrongly printed "70") as a result, it was said, of leg ulcers.—I am, etc.,

London, W.1

F. PARKES WEBER.

Significance of the Rh Factor

SIR,—In his letter in the *Journal* of Oct. 30 (p. 557) Dr. A. P. Bental makes, inadvertently, a most inaccurate and misleading statement. It is not correct to say that the children of a homozygous Rh-positive father (RhRh) and an Rh-negative mother will almost always suffer from erythroblastosis. In our article (*Journal*, Sept. 4) we pointed out that haemolytic disease of the newborn is very much rarer than it would be if it occurred in every family in which the father is Rh-positive and the mother Rh-negative. But once the disease has appeared all subsequent Rh-positive children will almost certainly be affected—very occasionally a later Rh-positive child is born apparently normal. Clearly, women vary greatly in the readiness with which iso-immunization to a foetal antigen occurs: thus we have observed families in which Rh-negative mothers have borne as many as six healthy Rh-positive children without miscarriage or stillbirth. Similarly, it has been found that many Rh-negative women transfused with Rh-positive blood fail to become immunized at all, even after repeated transfusions, whereas others develop antibodies after only a single transfusion. An Rh-negative mother is more likely to be

immunized when every pregnancy is Rh-positive and provide the antigenic stimulus as it does with a homozygous husband than when he is heterozygous and some of the children are positive and others negative. This being so, it is obvious that the proportion of homozygous fathers producing affected children will be greater than the proportion of heterozygous fathers, and from this it follows that in affected families there will be a shortage of Rh-negative children. In our series of 50 families the shortage of Rh-negative children may have been abnormally marked, and in later families we have occasionally found Rh-negative children; but our experience is that the homozygous father more frequently brings about iso-immunization of the mother than does the heterozygous father, and our opinion, unless the father of an affected child has disclosed himself as heterozygous, the chances of a subsequent child being born unaffected should be regarded as very poor. With a heterozygous father the chance of the next pregnancy being Rh-negative is one in two, and although an occasional later Rh-positive child will show no signs of the disease, the chance of a heterozygous father producing a normal child is only very slightly better than one in two.

By serological tests recently described (*Nature*, 1943, 153, 300, 563) it is possible to recognize the genotypes of a large proportion of persons and in many cases to say whether a man is homozygous or heterozygous Rh-positive; with this knowledge we can form a better estimate of the chances of unaffected children being born to couples who have had erythroblastic babies. These tests, owing to the scarcity of the necessary sera, cannot yet be made on a large scale, but the results confirm the opinion expressed in our paper that the proportion of homozygotes is higher among fathers of affected families than in the general population.

In Dr. Bental's case the occurrence of Rh-negative children shows that the father is a heterozygote, and it is to be expected that all the Rh-negative children would be unaffected. It is necessary to suppose that the first two children are Rh-negative; our table shows several families in which three Rh-positive children were born before the disease appeared.

Dr. Bental is right in thinking that the knowledge of unaffected children may be born will encourage those who have to supervise the pregnancy of a woman who has already had erythroblastic children. There is much more encouragement in the knowledge that adequate transfusion of the newborn with appropriate blood may save nearly all the affected babies, as Gimson suggested in this *Journal* on Sept. 4.—We are, etc.,

MARJORY N. MCFARLANE

Are Hospital Diets Adequate?

SIR,—Patients discharged from hospital complain that diet in hospital is not only insufficient but that it is badly cooked and served in an unappetizing manner, so that they often cannot eat the little they get and rely to a considerable extent on food brought to them by relatives. I have found patients suffering from surgical affections, which do not call for dietary restrictions, lose as much as 14 lb. in a month. They surrender their ration-books to the hospital authorities, who remove the food and "points" coupons. Although butter coupons are removed they complain that they are never given any butter during their stay.

It is certainly time that hospital feeding was investigated and hospital cooking. Adequate feeding would contribute materially to shortened convalescence, a matter of some importance in these days.—I am, etc.,

Brookwood.

H. M. STANLEY TURNER.

Sterility and Impaired Fertility

SIR,—The only point at issue between the two letters on this subject published on Oct. 16 (p. 493) and on Nov. 13 (p. 6) is concerning the relative importance of voluntary and involuntary sterility as causes of the decline in the population. The writers of the first letter, after a preliminary and confessedly limited investigation of the subject, have reached the conclusion that involuntary sterility is a more important factor in the decline than was previously supposed, whereas the writers of the second letter are inclined to disagree with them. The signatories are, however, in agreement that every aspect of it

important subject must be fully investigated. It is certainly not that no authoritative pronouncement on this question can be made until much more evidence becomes available, and that valuable data would be derived from census inquiries. It was with the object of calling wider attention to the need for a complete and searching investigation of the causes—economic, biological, and pathological—of the decline in the population that the earlier of the two letters was written. We are therefore grateful for the support given by the signatories of the second letter to the need for this investigation, even although they are of the opinion that the economic causes are of greater importance than the factor of involuntary sterility.—I am, etc.,

KENNETH WALKER.

Chairman of the Subfertility Conference of the
British Social Hygiene Council.

London, W.1.

Contraception and Sterility

SIR.—Mr. V. B. Green-Armytage appears to have a highly laistic mind, if one can judge by the last two publications in the *Journal* to which his signature has been appended. In the first letter (Oct. 16) it is stated:

"... In one group (numbering more than 200 women) of regular users of birth control the average number of children was higher than a comparable group of women using the same methods intermittently. Further investigations show that the contraceptive methods most commonly used by the industrial population—'artificial and infertile alike'—are notoriously unreliable (coitus interruptus and soluble pessaries); their seeming success, to which many working-class women attribute the small size of their families, can be shown to reflect lowered fecundity in at least one-third of the cases (about 100) investigated." In other words, he accepts the inference that, given a higher degree of fertility on the part of the couple concerned, it will bear fruit in spite of attempts at contraception, whereas the fundamentally subfertile couple will achieve a small family by using quite unreliable methods of birth control regularly—i.e., they are subfertile anyway and birth control is not responsible.

In his letter published on Oct. 23 he writes: "The deduction is that anything or any method which prevents, retards, or alters the normal degree of physiological absorption of human semen from the vagina carries with it during the early months and years of matrimony the risk of future sterility from failure of uterine development and endocrine asynchronization." In support of this theory he cites two extremely small series (20 cases in each group): Group 1 had used no contraceptives of any sort; Group 2 had used some form of birth control throughout marriage (chemical douches, caps with medicated pessaries, condoms, or coitus interruptus).

Even in his original paper he does not tell us the ages of these women, how long they had been married, the frequency of coitus, whether the husband's semen had been examined in each case and with what result, nor whether the patients in either group received treatment of any sort. He simply tells us that in both groups conception occurred in 25% of cases as soon as it was tried for; that in the first group 15 had, in his opinion, hypoplastic uteri, 9 of which grew to proper size in 4½ to 6 months; and that in Group 2 10 had hypoplastic uteri, but he does not tell us what they were like at the end of 6 months. Yet from this tiny series he is prepared to make the above deduction, attempting to support it by quoting the results of a few experiments with spayed immature female rats and immature female rabbits, which were injected intramuscularly or intravenously with human semen. These animals showed muscular and glandular development of the uterus and, in the non-spayed, hypertrophy of the ovaries. "Preliminary experiments," he writes, "indicate that full development of the female genitalia is due to the absorption of hormones by the vagina from the human semen," though there is nothing in his experiments to prove that absorption does and can occur from the vagina nor what it is that is absorbed. He quotes Noble (*J. Endocrinol.*, 1939, 1, 184), who worked with synthetic testosterone propionate and not semen, and who produced various complex changes by injections of this hormone (sometimes combined with other hormones) given subcutaneously to rats, but does not quote Goldblatt (*Biochem. J.*, 1935, 29, 1346), who, working with fresh human semen injected intravenously into young virgin rabbits, failed to produce any changes in the uterus or ovaries. He mentions the late Sir Francis Fremantle's recent statement in the House but does not refer to Dr. Gibbon Fitzgibbon's letter in the *Journal* (Sept. 11, p. 350) despite the latter's infinitely wider practical experience.

Mr. Green-Armytage then goes on to accuse contraceptive methods of attacking the arbor vitae and producing a cervicitis with subsequent cervical blockade, apparently ignoring the frequent association of a very typical and non-infective cervical blockade with endocrine dysfunction and genital hypoplasia, which, by the time he has reached his last paragraph, he is attributing rather to some harmful but unspecified influence on the growing girl's constitution

and endocrine system than to the absence of semen in the adolescent vagina. Surely this is too important a matter for such wild assumptions. If, indeed, the use of contraceptives, more particularly by women in the younger age groups, is threatening fecundity, the sooner this is proved by properly controlled and adequate observations the better. If, on the other hand, quite different factors are responsible they must be unearthed and necessary action taken.

He ends by saying that it is irrational to set up petty sterility clinics to deal with the problems of subfertility, and that the work must be in the hands of properly staffed and equipped hospitals; but what the hospitals gain on personnel and equipment they lose on lack of time, intimate personal contact, and co-ordination. The hospitals have not at present time or space to cope adequately with the very great number of people, up and down the country, who want advice on subfertility; some in consequence are doing shoddy work, and many patients are frustrated in their efforts to get adequate investigation and treatment. Family Planning Association clinics have a definite role to fill; by creating a demand for good and thorough work they may galvanize the hospitals into more effective action, and they can act as sorting and co-ordinating centres and as sources of material for research. Why should they, as Mr. Green-Armytage suggests, be cut off from the team work of their local hospital? They should be in constant and close touch with it and have the advice and help of its consultant staff. Moreover, what general hospital has such easy access to large groups of *superfertile* patients as are available at F.P.A. clinics to act as controls in the many difficult problems confronting those who attempt to investigate, diagnose, and treat *subfertility*?

—I am, etc.,

Crednon.

MARGARET HADLEY JACKSON.

SIR.—It is most depressing that the preventive aspect of sterility should make so small an appeal to Dr. Malleison. In her first letter she merely asked for information. Physiological, pathological, biochemical, electro-potential, and clinical evidence was provided to show incontestably that mechanical plus chemical contraceptive measures before the first conception are deleterious. Seeing that the greatest living authorities on sterility were quoted—Rubin, Kurzrock, Miller, Meaker, and Ségué, men whose calibre, research, and team work we have so far been unable to match—it is no good being squeamish or peevish. No opposing or unbiased views of any real weight can be found to gainsay clinical facts that are easy of proof. It is, however, comforting to see in the latest editions of their textbooks that Blair Bell, Beckwith Whitehouse (Eden and Lockyer), and J. H. Peel (Forsdike), on pages 336, 215, and 341 respectively, all support the opinion that such methods are injurious from the point of view of future conception. For the rest *quod scripsi scripsi*.—I am, etc.,

London, W.1.

V. B. GREEN-ARMYTAGE.

Early Diagnosis of Cancer

SIR.—It would appear from Dr. J. F. Brailsford's letter (Oct. 30, p. 555) that he would have the general public kept in ignorance of the early symptoms of cancer despite the consequences. I find his arguments difficult to follow. No one wants it advertised on hoardings; in fact, the hoardings which so desecrate our landscape are largely disappearing from the country, and we all hope that ultimately they will be eradicated.

That a few out of the thousands of cases dealt with by radium or x-ray therapy have been made worse and their sufferings increased merely indicates that we have not reached perfection, that cases have been badly selected or improperly dealt with. Failures and mistakes will have been made in all branches of medicine and in any other walk of life. The most likely source of failure in radiotherapy, and one which may lead to much unnecessary suffering, is the attempt at radical therapy in cases unsuited or too advanced for such treatment. The same applies to surgical treatment of the too advanced, such as radical mastectomy for late carcinoma of the breast and many other procedures of like description, where a major operation planned on the best lines may only lead to further suffering. We need team work and better co-operation between the different specialities in order to select the best treatment for each individual case. Carcinoma of the rectum is a good example. An advanced case with a fixed ulcerating growth and stenosis of the bowel may derive no benefit from radiotherapy, and is likely to be caused greater suffering by attempts at radical therapy by radium. It is surely the aim of all of us to relieve suffering, and no body of people realize this

better than those who devote their full time to radiotherapy and to whom these patients so often turn for treatment and assurance. The therapist or surgeon who treats the disease and forgets the patient is making a mistake.

As regards statistical incidence of cancer, this will continue to rise everywhere until 100% of cancer cases are diagnosed as cancer. One thing we can be pretty sure about is that a cancer case will not get better without treatment, and that in the majority of cases there is a point at which it will become hopelessly incurable. It is because we do not know just precisely when it becomes incurable that we do not regard cancer as an "acute" or "semi-acute" surgical condition. We know from statistical reports that a perforation of the bowel if left more than 30 hours has most likely been left too long, and we would deprecate the delay. The same applies to a cancer case if we substitute days or weeks instead of hours, and we know from experience that a carcinoma of cervix or uterus with symptoms for 30 weeks has little chance of survival, and that there is some particular time when such a case crosses the line that separates those which are curable from those in which the patient will suffer from "recurrences" and ultimately die from the disease. Here are some statistics from one centre to show just what proportion are on the wrong side of that line. Similar figures will be found all over the country.

Carcinoma of Cervix, 1929-35

Stage	No. of Cases	No. Died of Cancer	No. Alive 5 Years	Died of Other Causes or Lost Sight of
III or IV ..	257	213	36	8
I or II ..	162	76	75	11

From this we see that three-fifths of the cases applying for treatment were hopelessly inoperable; they had a one in seven chance of a five-year cure by radiotherapy, and it is questionable whether it was really worth while treating more than half of them. Only two-fifths came at the stage where they had a 50% chance of cure. If those 419 cases came at the earliest possible sign—if they were all Stage I cases—they would have about 80% chance of cure even with present methods, which may leave much to be desired, and we have not yet got down to screening the radiation from the rectum and perfect distribution of the radium.

Now, why should children lose their mothers (or fathers) because their parents are kept in ignorance of the early signs of cancer? It is fear and ignorance which stop them coming. Do we think that the public "cannot take it"? Experience teaches us that we can always take the truth better than deception. By this I do not mean that we should tell the patient that he or she is suffering from cancer, or use the brutal phrase which Dr. Brailsford has put into the mouth of the cancer expert: "You know what is the matter with you, missus; you've got a cancer." What we want is for the public to know that tumour, especially one which is painless, requires prompt attention. The incurable cancer case we must continue to live and console with palliative treatment or placebos and analgesics, and may we be forgiven for the deceptions we practise!

But what harm in educating the public just a little? Why not make a start? I would suggest that the last page or two of the first-aid books which are so popular might have a little space devoted to pointing out what are the "early signs of a tumour," and might give just enough information to enable the reader to recognize when he or she should attend a doctor for advice. It could be worded to give assurance and to encourage early treatment. If we could get it across to the first-aiders it would not be long in reaching the majority of people. Then we might get our cases before they are too late, and our results would be more encouraging.—I am, etc.,

GEORGE W. BLOMFELD,
Medical Director, Sheffield Radium Centre.

Radiology—Empiricism or Science?

SIR.—In the November issue of the *British Journal of Radiology*, writing under this title, Dr. A. E. Barclay presents a most interesting review of the progress of radiology, and also a timely warning about the present critical phase through which radiology is now passing.

It does seem to-day that radiology, and, in fact, radiologists require a lead, and Dr. Barclay's article puts forward a sound and useful proposition to steer radiology on the right course in the future. He advocates a "radiological research institute" devoted solely to the study of the body in health in order to establish a reliable basis from which to assess the pathology and asks whose duty it is to establish such an organization.

While wholly in agreement with his suggestions I would like to even further ahead. For some time back many of my colleagues and I have felt that radiological affairs in this country require a lead from one body by the formation of a College of Radiology. In this college a large section would be devoted to research as Dr. Barclay advocates, while there would also be a teaching side for radiologists and radiographers with the appropriate examinations for higher and lower diplomas. Various types of equipment (for teaching purposes) might be placed at the disposal of the college by the various x-ray manufacturers which indirectly would prove to the manufacturer an excellent show place for his products.

That radiology in this country will undergo some form of reorganization seems the common feeling, and the existing societies do not just meet the case. To my mind here is an opportunity and almost a duty for the British Institute of Radiology to rise to the occasion and create a College of Radiology from its present organization, and thus cement the unity of radiologists and give a lead to this important scientific both in this country and, after the war, to those multitudes of radiological remnants throughout devastated Europe.—I am, etc.,

London, W.1.

NORMAN P. HENDERSON

X-ray Diagnosis in Pulmonary Tuberculosis

SIR.—Dr. J. S. Sharpe in his memorandum (Nov. 6, p. 1) has pointed out the shortcomings of radiography in the diagnosis of a case of pulmonary tuberculosis. He has, however, failed to appreciate that there is no such thing as x-ray diagnosis in pulmonary disease, nor yet in many other types of disease, but there is x-ray evidence.

In pulmonary conditions the similarity between various radiological appearances is such that the failure to approach the case from every angle courts error in diagnosis and disaster. Apart from the usual clinical and pathological investigation, family and occupational history must be considered. This has been forcibly impressed upon me and stressed by me during twenty years' radiological practice in a mixed agricultural and industrial area. Dr. Sharpe's patient certainly received a clinical investigation, but one cannot help wondering what later radiograph would have revealed. The radiological appearance of lung pathology frequently changes rapidly. Most radiologists of experience are alive to the limitations of x-ray radiography. There are limitations in every field of investigation.—I am, etc.,

Ulverston.

RICHARD FAWCETT

Unpadded Plaster in Open Wounds

SIR.—Undoubtedly many lives and many limbs have been saved by the modern treatment of compound fractures—adequate excision of dead and devitalized tissues, removal of foreign bodies, blood clot, and detached fragments of bone followed by the application of sulphonamide powders, a fixation in plaster. In all papers on this subject great emphasis is laid, and rightly so, on the necessity for thorough cleansing of the limb and wound, for all aseptic precautions, "no-touch technique," changing of gloves and instruments, etc.; but one may say the same for the ritual during the second part of operation—namely, the application of the plaster? When this stage is reached asepsis in many clinics simply ceases. One sees plaster bandages unwrapped by ungloved and even washed hands (in the surgical sense) and plaster slabs prepared on tables with unsterilized surfaces. These bandages and slabs are then soaked in unsterilized water in unsterilized buckets and handed to the surgeon or assistant, who applies them to the open and unprotected wound.

Should we not insist that plaster bandages and slabs be sterilized before they leave the manufacturer and that all aseptic precautions are observed during the unwrapping, handling, and soaking?—I am, etc.,

Dundee.

F. R. BROWN

D. and V. and Mastoiditis

SIR.—I am grateful to Dr. Ellison for pointing out an error of logic in my letter (Oct. 23, p. 526). The sentence he justly criticizes would convey my meaning better should it read as follows: "In all cases of D. and V. and dehydration in which bacteriological examination of the faeces proves the absence of a specific organism the diagnosis of gastro-enteritis, if made, is probably incorrect, and the possibility of mastoiditis should be considered as a likely cause of the symptoms. If in such case D. and V. and loss of weight continue in spite of dietetic, saline, and sulphonamide treatment, and if, in addition, the child is restless, puts his hand to his head, has a bald patch in the back of his head and enlarged glands in the posterior triangles, the diagnosis of progressive mastoiditis is almost certain. Such cases should be promptly handed over to the oral surgeon for surgical treatment, for progressive mastoiditis treated medically is a fatal condition."

I would remind Dr. Ellison that the condition to which I refer is one which is present only in infants; his remarks concerning ulcerative colitis and arsenical poisoning, somewhat tinged with sarcasm, are therefore irrelevant.

My letter was an attempt to show that even apart from universal breast-feeding much could be done by both prevention and cure to lessen the death rate among infants diagnosed as gastro-enteritis if its aetiology were more generally realized. It was not intended to arouse antagonism.—I am, etc.,

P. W. LEATHART.

Liverpool.

"Opponents of the Medical Profession"

SIR.—In his letter in your issue of Nov. 13 on "Opponents of the Medical Profession" Mr. Rugg-Gunn, seeking to show that his policy and his *Bulletin* are not anti-Semitic, writes that "quoting the book *Protocols of Zion* we were careful to indicate that there are doubts as to its authenticity."

There is an error here. There are no more doubts as to the authenticity (or probability) of this disreputable anonymous forgery than of the series of closely similar fantasies set forth by that accurate historian Adolf Hitler, in his *Mein Kampf*. That authority has also made many constructive suggestions for a medical policy, which Mr. Rugg-Gunn has doubtless studied. Some may be garnered from the pages of the vast volumes of *Hitler's Speeches*, edited by Prof. Norman Baynes.

Mr. Rugg-Gunn will find a complete and detailed demonstration of the unsavoury origin and fantastic nature of the moss-grown booby-trap in which he has been caught in *Portraits of Mean Men, A Short History of the Protocols of the Elders of Zion*, by Mr. John Gwyer, published in 1938 by Messrs. Cobden-Sanderson. Mr. Gwyer shows—perhaps for the hundredth time—that the main framework and much of the phraseology of the "Protocols" are taken from an attack on Napoleon III, first published at Brussels in 1865 as a romance under the title *Dialogues aux Enfers entre Machiavel et Montesquieu*, which has nothing whatever to do with Jews. The subsequent history of this paltry romance and its modification into its present form is an extremely complicated story. It has been traced in minute detail, but here it must suffice to say that the inglorious author was an obscure scribbler, one Maurice Joly (1831–78) of Lons-le-Saunier in the Jura, who, not inappropriately, died by his own hand.

Despite his zeal for accuracy Mr. Rugg-Gunn quotes wrongly the title of the obscene booklet, the authenticity of which he must be allowed to doubt if he prefers to do so.—I am, etc.,

The Athenaeum, Pall Mall, S.W.1.

CHARLES SINGER.

SIR.—I congratulate you on at last raising the ban on the mention of the Medical Policy Association, even though it be in order to misrepresent it (*Journal*, Oct. 30, p. 552). Your attempt to prove by false logic a connexion, where in fact no connexion exists, between it and Nazism and what is inaccurately called anti-Semitism is hardly worthy of an annotation in a journal concerned with the scientific method; nor is your rather scornful reference to a distinguished member of our profession. Moreover, it is a propagandist device too well known even to the most unsophisticated of your readers to succeed in its purpose.

As one who for years has been working for an objective closely corresponding to that of the M.P.A. (as former letters

to you testify) and who has been connected with this association from its early days, though not actually a founder member, I emphatically assert that, unlike the panel system, by means of which official B.M.A. threatens to extinguish private practice, the M.P.A. draws none of its inspiration from enemy ideology, and there is not even a shadow of foundation for those statements of yours which border on the libellous. If, indeed, they have not offended against the law. The M.P.A. is not frightened by an attack such as yours. It has nothing to hide. It is based on truth and reality against which its would-be detractors can make no headway. Nothing would be more pleasing to its members than to have the attention of the whole profession directed to its origin, aims, and methods.

There are other organizations—the Fabian Society, the London School of Economics and Political Science, and Political and Economic Planning—to which you refer in your article, and about which you appear to be as ill informed as regarding the true nature of the Medical Policy Association. Can you say whether these organizations are as willing as is the M.P.A. to have their ultimate objectives brought into the clear light of day? What is the relation of their activities to present-day political movements both within and without the medical profession? Have they any connexion with the tendency which you deplore in your article "Misrepresentation" (*ibid.*, p. 549) to make the line of medical development an issue of party politics?

I would suggest that anybody who cannot give satisfactory answers to these questions and others like them might be profitably employed in digging down to the roots of things, in exploring the sources from which political movements arise. In this connexion a useful exercise would be to make an investigation whether there is any foundation for the following statement which a Mr. Benjamin Disraeli (afterwards Lord Beaconsfield) puts into the mouth of a character in one of his novels: "So you see, my dear Coningsby, that the world is governed by very different personages from what is imagined by those who are not behind the scenes." How difficult it is for the ordinary personage to get even a peep behind the scenes!—I am, etc.,

Bexley, Kent.

E. U. MACWILLIAM.

SIR.—Your timely castigation of Mr. A. Rugg-Gunn and his friends in the issue of Oct. 30 called forth a letter from him which you published on Nov. 13. There does not appear to be anything in this correspondent's letter to justify a reply, as it is what the German military authorities call a "disengagement" from an awkward situation; but it is worth while to recall a letter in his usual vein by this same correspondent which was published in the *Lancet* in October, 1939, and which was severely dealt with by subsequent letters in the same journal.—I am, etc.,

Golders Green, N.W.

L. S. WOOLF.

* * We have had a number of letters reinforcing those from Prof. Singer and from Dr. Woolf, but the correspondence must now be closed.—Ed., B.M.J.

Therapeutic Fallacies

SIR.—The up-to-date tuition given by Drs. Linnell and Thomson in their paper on therapeutic fallacies prompts some qualifying reflections.

1. Case management suitable in hospital consulting practice may not be fitting in general practice. A patient is not the same person in both settings, the doctors differ in prestige and use and duration of personal service, and the things to be known also differ. Patients come to the G.P. to find out all that the hospital doctor did not tell; G.P.s issue certificates and patients read books; a great many patients think they have "blood pressure" before they come for its measurement; and so on. A patient likes to be told as much truth as he can straightway be taught to bear. Truth-telling provokes "reality-thinking": power to reassure depends on a proved lack of duplicity in the doctor; an anxiety state is best prevented and cured by understanding, anticipating, and balancing the patient's own inner thoughts and feelings.

2. Experimental conditions often differ in essentials from those of clinical experience. Clinically alcohol has a twofold effect, exciting in one way and depressing at the same time

in another way; dosage and circumstances may decide whether stimulation or depression prevails in the total effect. Very small doses and small variations of doses of digitalis cause subjective effects in some senile patients with slowly failing hearts. Assuming that a calcium salt "in some cases of chilblains seems to act like a charm" (Norman Walker) it is inconclusive to object that in all cases "the serum calcium is normal." Even if the objection be relevant, would one argue that a man's donations to persons and to charitable agencies could not bear any relation to his income because his deposit at the bank remained at the "normal" figure?

3. Drugs are not really things endowed with their own power to act; they are substances active in relation to living things and circumstances. Hence a remedy becomes an organismal "poison" only when inappositely prescribed or when given to the right patient in excessive dose. Hence also one should not expect a remedy to give consistent results in all patients or in all disease conditions given the same label. Sulphapyridine may settle a run of cases of tonsillitis within 24 hours in every case; the first failure may or may not indicate a newly arrived infection and give a different remedy a prosperous run. Pulv. ipecac. \bar{c} opio may be either curative or simply emetic on the first night of a "cold," and the same kind of remark applies to various proprietary remedies. Surely the failures have no greater validity than the successes! Surely what is wanted in both events is more adequate discrimination of conditions, as has been largely done for iron and cod-liver oil. Meantime it is often the so-called uncritical impressions of G.P.s which silently decide the retention or discarding of a therapeutic novelty.

4. Large-scale statistics may contain large-scale error from insufficient differentiation of groups of cases. Injecting a multitude of factory employees with anticatarrh vaccine all on the same day does not seem a convincing experiment. Some employees come to the G.P. in a day or two suffering from a cold and seemingly worsened by vaccine given at the wrong time.

In short, there are canons of scepticism as well as canons of belief.—I am, etc.,

Greenford.

W. THOMSON BROWN.

SIR,—A little iconoclasm is frequently salutary in a profession such as ours, which tends to become conservative, and I find much to agree with in Linnell and Thomson's article (Nov. 6, p. 572). I would suggest, however, that their article would be of greater benefit if they could suggest treatment, or, rather, prophylaxis which really works for some of the complaints they list. Can they say, for instance, that enemata will in the end break the constipated habit? As treatment it is unarguable.

As regards the common cold, I will join issue with them. My experience is based on the results of injections in a factory, where 70% of those injected were improved. This is, in my opinion, sufficient justification. The remaining patients for the most part were found to have some cause for their colds, such as sinus infection. I do not claim more than benefit, though a reasonable percentage of patients receive, apparently, immunity.

Have the authors *nothing* constructive to say about chilblains? And, finally, are they unaware of the possibilities in the use of testosterone propionate and nicotinic acid in the treatment of angina pectoris? No one claims that glyceryl trinitrate is anything more than a palliative.—I am, etc.,

Dorchester.

T. RUSSELL STEVENS.

Reporting Deaths to Coroners

SIR,—Owing to uncertainty as to the obligations of medical practitioners to report deaths to coroners, the Medical Defence Union and the London and Counties Medical Protection Society have received a number of inquiries from their members as to the legal position. The above-named societies accordingly obtained the opinion of Mr. Roland Burrows, K.C., of which the following is a summary authorized by him:

1. There is no legally enforceable duty resting on a practitioner, acting as such, to report any death to a coroner.
2. The coroner has no power to require a practitioner to report any death to him.
3. It is the duty of the registrar of deaths to report deaths in certain circumstances to the coroner:

4. A practitioner must not do anything to obstruct the coroner in the discharge of his office.

5. A practitioner may make a post-mortem examination of the consent of the deceased's relatives, whether or not he is the cause of death, unless by so doing he knowingly hinders the coroner in carrying out his duties; but, as soon as it comes to knowledge of a practitioner that the coroner has been informed from any source touching the death, on no account should examination of the body be made without instruction from the coroner.

We have stated above the legal duties of practitioners, they, like other members of the community, have social, public and moral obligations not enforceable by law to assist coroners. It is important that practitioners and coroners should collaborate harmoniously for the public good, and it is hoped that a practitioner will refer to the coroner any death respecting which he feels any doubt. A copy of Mr. Roland Burrows's opinion upon which the above is based, can be obtained by memorandum on application to the Secretary of the Medical Defence Union, 49, Bedford Square, W.C.1, or of the London and Counties Medical Protection Society, Victory House, Leicester Square, W.C.2.—We are, etc.,

JAMES FENTON,
President, Medical Defence Union
CUTHBERT WALLACE,
President, London and Counties
Medical Protection Society.

Obituary

JOHN LEVIS, M.B., B.Ch.

Mr. John S. Levis, honorary assistant surgeon, Royal Ulster Hospital, Bath, and consulting surgeon to the Orthopaedic Hospital at Combe Park, died suddenly at his home in I. down Park on Nov. 5. He studied medicine in Cork, Dublin and took the Irish triple qualification in 1912, followed this a year later with the M.B., B.Ch., B.A.O. of the National University of Ireland, which conferred on him its M.Sc. *de honoris causa* in 1920. Mr. Levis began his service at the Royal United Hospital as resident medical officer, and on settling practice at Bath became honorary anaesthetist. After the war, during which he held the temporary rank of Major R.A.M.C., he was senior medical officer for the city under the Ministry of Pensions. He had a widespread surgical practice in the adjacent parts of Somerset and Wiltshire, and was consulting surgeon to the Malmesbury Hospital, the Victoria Hospital, Frome, and the Trowbridge, Melksham, and Shepton Mallet Hospitals. Joining the B.M.A. in 1919 he held office of honorary secretary of the Section of Orthopaedics at the 1st Annual Meeting in 1925, and was chairman of the local Division in 1929-30. He was also a member of the International Society of Surgeons and of the Bristol Medico-Chirurgical Society.

A colleague writes: With the death of John Levis the profession has suffered a grievous loss. His value to the community can be assessed merely in terms of his undoubted professional skill. He had attributes of character which would have made him an immense influence for good in any profession he had chosen to follow. He had the gifts of simplicity, physical and moral courage, directness and honesty, to a degree too rare in these days. He was tough where necessity demanded it, but his toughness was more respected when evaluated against the background of kindness and charity which was his essential nature. He was an underdog's friend and an indomitable fighter for just causes. He weighed up his actions according to the principles of ethics and despised the idea of expediency. He was unfailingly charitable to the afflicted, the soul of generosity. The world is poorer for his loss, and Bath have suffered not only a grave impoverishment of our efforts as a medical community, but an incalculable depletion of our valuable forces of character. Another colleague writes: The sudden unexpected death of Mr. Levis came as a great shock to every one who knew him, not only in Bath but far outside the confines of the city. As a surgeon he was gifted with great powers of observation and diagnosis and was strongly opposed to routine methods, always striving for improvement, and before the war devoted his time to visiting the great surgical clinics of Europe. His colleagues will deplore his loss, as do hosts of patients, who will miss his cheerful and friendly personality. After the air raids on Bath his home was crowded to overflowing with the homeless, for whom he was not do enough, while his platoon of the Home Guard were made welcome. The little spare time he had was spent in his garden where the writer had the privilege of passing many happy hours.

him. He was a straightforward honest man, a staunch friend never spared himself, and a wise counsellor to whom nobody appealed in vain for help or guidance. Only his closest friends any idea of the extent of his charity. Jack Levis set a shining example of unselfish service and self-sacrifice.

We regret to announce the death at Brighton on Nov. 15 Dr. LOUISA GARRETT ANDERSON, C.B.E. Her father was G. S. Anderson, shipowner, and her mother was Elizabeth Garrett Anderson, M.D., the pioneer medical woman in this country, whose life-story she told in a book published in 1939. She was born on July 28, 1873, and from St. Leonard's School, Andrews, went to the London (Royal Free Hospital) School of Medicine for Women, graduating M.B.Lond. in 1897 and in the M.D. in 1900. After serving as house-surgeon at the Royal Free Hospital she became in turn house-surgeon, house-physician, and assistant surgeon to the New Hospital for Women, and then surgeon to out-patients at the men's Hospital for Children, Harrow Road. In Sept., 1914, Dr. Louisa Garrett Anderson went to France as joint organizer of, and chief surgeon to, the Women's Hospital Corps voluntary unit. She returned to London in 1915 to take up the post of chief surgeon at the newly opened military hospital in Endell Street, and worked there until after Armistice. For her war services she was created C.B.E. She joined the B.M.A. in 1898 and was honorary secretary of the Section of Obstetrics and Gynaecology at the Annual Meeting of 1905. On retiring from practice some years ago she made her home at Paul End, Penn., and was appointed a Justice of the Peace for the County of Bucks. Besides the biography of her noble mother she wrote a number of papers for medical journals and contributed the article on peritonitis to the *Encyclopaedia Medica*.

Dr. SAMUEL HEY died at Ripon on Sept. 28, aged 73. He is the only son of Samuel Hey, F.R.C.S. (1815-88), the Leeds surgeon whose grandfather, William Hey I, had been active in founding the General Infirmary at Leeds in 1767. Dr. Hey was educated at Tonbridge School, Trinity College, Cambridge, and St. Bartholomew's Hospital. He qualified in 1900, and after serving as house-physician at Bart's and R.M.O. of the Royal Chest Hospital, settled in general practice at Ripon, where he became surgeon to the cottage hospital, medical officer to the workhouse, and in 1904 deputy coroner for the Ripon district. He joined the B.M.A. in 1908 and was a member of the West Riding Medico-Chirurgical Society and the Arrogate Medical Society.

Dr. JOHN NEWBURY FERGUSSON, who died at York on Oct. 1 aged 62, was born at Wick. After three years at St. John's College, Cambridge, he went to St. Thomas's Hospital. He qualified in 1905 and till 1913 he practised at Malvern. In 1914 he went to Plymouth and from there joined the R.A.M.C. in 1915 to 1919 he was radiologist in No. 8 General Hospital at Rouen, and while he held that post he contributed to the *B.M.J.* an article on a new system of location and traction of foreign bodies in the brain. In 1919 he became Fellow of the Royal College of Surgeons of Edinburgh. In 1920 he went to York and in 1924 he became honorary radiologist to the York County Hospital. Up till three weeks before his death he gave unstinted loyal service to that hospital. He leaves a widow and a son and daughter; his son a surgeon in an L.C.C. hospital. A colleague writes: "Newbury Fergusson's death is a great loss to the medical profession in York and district. His knowledge of medicine and surgery, added to his skill in radiology, which included a technical genius and ingenuity in engineering, was always at the disposal of his confrères. If patient endeavour and conscientious striving to throw light on a difficult case were needed Newbury could be relied upon to provide these in full measure. He entered whole-heartedly into every phase of medical activity in the district and had held the offices of chairman of the York Division of the B.M.A. and president of the York Medical Society. In all his work he rightly enjoyed the respect and confidence of everyone in the profession. He was quiet and modest by nature, and work was his hobby. Latterly he carried on when those who knew him realized that he should be taking things more easily, but to spare himself was not the way in which he was built. He served his generation truly and well."

Dr. ARCHIBALD OLIVER, of Thetford, Norfolk, died in London on Oct. 4, aged 62. He was the third son of the late Archibald Oliver of Edinburgh, and studied medicine at Edinburgh University, graduating M.B., Ch.B. in 1904 and taking the M.D. and D.P.H. in 1908. He had been M.O.H. for the Thetford Urban District Council since 1912, when he settled in that town. He served in the war of 1914-18 in the R.A.M.C. and was D.A.D.M.S. at Salonika with the rank of major; he

received the Greek Order of St. Saviour and the Médaille des Epidémies in recognition of his work on malaria in Greece. Dr. Oliver took a great interest in public health work and started the Thetford maternity and child welfare centre. He was also president of the local branch of the British Legion, a Justice of the Peace, and a governor of the Thetford Grammar Schools. He joined the B.M.A. in 1908 and had held office as president of the Norfolk and Norwich Medico-Chirurgical Society. He was a keen golfer and angler. His death is a great loss to Thetford and district.

We regret to announce the death on Oct. 6 of Dr. ESSEX FRANK WAKE NIXEY, medical superintendent of St. John's Hospital, St. John's Hill, S.W.11. A medical student of Edinburgh University he graduated M.B., Ch.B. in 1908 and was appointed an assistant medical officer at St. John's Hospital by the Guardians of the Wandsworth Union at the beginning of 1909. He became senior medical officer in 1910 and deputy medical superintendent in 1913, and after transfer to the L.C.C.'s service in 1930 he became medical superintendent on April 1, 1933. Dr. Nixey thus spent the whole of his professional life at St. John's Hospital, and the Hospitals and Medical Services Committee of the L.C.C. has recorded that his long period of service was characterized by ability and zeal. He was particularly interested in psychiatry and made an outstanding success of his work in connexion with the large mental observation unit at the hospital. "His death is a grievous loss to the service, and his unfailing and sympathetic understanding and co-operation will be remembered with gratitude by patients and colleagues."

The death on Oct. 7 of GEOFFREY REMINGTON WILSON has removed a well-known and universally respected figure from the Essex town of Ongar. Wilson was born in 1874, educated at Aldenham School and Trinity College, Cambridge, where he graduated M.B., B.Ch. He learnt medicine at the London Hospital, where he held house appointments, and was also house-physician at Paddington Green Children's Hospital. In 1902 he succeeded to the practice of Dr. Grattan, Ongar, and conducted it up to a short time before his death over forty years later. Wilson was a man of diverse interests and busied himself with local affairs. He was chairman of the bench of Magistrates and of the Public Health Committee in the district council. He was a keen sportsman and played games well, besides being a good Latin scholar and well read in English literature. He was a prime mover in the founding of the Ongar War Memorial Hospital and an active worker in its wards. He will long be remembered for his kindly disposition and by his professional brothers as a loyal and honourable colleague. He joined the B.M.A. in 1902 and was chairman of the Essex Division in 1933-4.

Dr. EDWARD HULSE WILLOCK of Exeter died on Oct. 10 at the Royal Devon and Exeter Hospital, aged 75. He studied medicine at St. Thomas's Hospital, took the L.S.A. in 1891 and the M.R.C.S., L.R.C.P. in 1892, and then practised for a long time in Croydon, where he was surgeon to the War Hospital and assistant surgeon to the Croydon General Hospital, and later medical referee for the Ministry of Pensions. Dr. Willock had been a keen and active member of the British Medical Association, which he joined in 1899; he was a past honorary secretary of the Croydon Division, and from 1912 to 1920 a member of the Central Council. He also served on various committees and subcommittees at headquarters and represented his Division at seven Annual Representative Meetings. Before he went to live in retirement at Exeter he had been a J.P. for Croydon, and in recent years he was chairman of the National Service Medical Board, Exeter.

Prof. Grey Turner writes: Dr. H. E. GAMLEN, whose death was recorded on Oct. 16, was one of the pioneer workers in x rays, and especially on the therapeutic side. In the early part of this century, while in practice in West Hartlepool, he was not only treating lupus and rodent ulcer by x rays but also other types of malignant disease. From time to time he showed cases under treatment at the Northumberland and Durham Medical Society, and at the November meeting in 1904 he presented an example of epithelioma of the tongue in which the Roentgen treatment had been supplemented by the application of radium. This powerful element was in the form of radium bromide, which was kept in a glass tube in a thermometer case and was usually carried in the waistcoat pocket! There was no applicator and the tube was merely held in contact with the affected area. In view of the disappearance of the growth there were those who doubted the diagnosis in that case in spite of the pathological reports which Gamlen produced. But after some months there was a recurrence which was removed by operation, and it was then shown that the tissues were infiltrated with squamous epithelioma. In later years Gamlen

used to explain that in those early days he knew nothing whatever about the harmful effects of irradiation, but it was none the less relentlessly laying the foundation of that distressing dermatitis which was so marked in his case and which was ultimately followed by the development of epithelioma. In the course of years he submitted to many mutilating operations before the disease finally led to the inevitable end. His sight became much affected and deafness supervened, but I never heard him complain. He was always enthusiastic and enjoyed his hard work, and when about 10 years ago he had to give up practice finally on account of increasing disability he took up breeding dogs with great zest and with great success. His name certainly deserves to be recorded on the roll of x-ray martyrs. (During the last war he was attached as consulting radiologist to the Italian, not the Indian, expeditionary force as mentioned in your notice.) Gamlen had one son, who predeceased him, and is survived by his wife, who watched over his latter years with singular devotion.

Dr. PHILIP THEODOSIUS JONES of Coleford, near Bath, died suddenly on Oct. 21. A student of St. Bartholomew's Hospital he qualified M.R.C.S., L.R.C.P. in 1896, and in 1932 he retired from practice and received a presentation at Coleford from a large number of friends and patients—a framed and illuminated address on vellum and a cheque which at Dr. Jones's wish was used to equip the Bath Royal United Hospital with a portable x-ray apparatus. He had been a member of the British Medical Association for 43 years.

Dr. J. A. WAIN, who died on Oct. 25, graduated M.B., B.Ch. at the University of Witwatersrand, Johannesburg, in 1929. After various hospital appointments and some general practice he came to this country and took his Edinburgh F.R.C.S. in 1938. Shortly afterwards he was appointed to the staff of the Radium Institute at the Christie Hospital, Manchester, where he quickly assumed many responsibilities, and where he remained until his death. At the outbreak of war Mrs. Wain and a young daughter returned to South Africa, but Dr. Wain remained, as he would have been happy to put it, in the service of this country. In all his activities, whether in therapy, in teaching, at children's parties, or in digging for victory, Dr. Wain could be counted on for a lively contribution, springing from an energetic personality which knew how to combine enthusiasm with a remarkable capacity for taking pains. As a member of the Radium Institute team his knowledge, criticism, and unflinching generosity contributed largely to its effective working. His unexpected death after an operation, at the age of 38, is indeed a lamentable loss to radiotherapy, and will be painfully felt by his many friends both in and beyond professional circles. His best memorial is a substantial record of scrupulously careful and successful work.

Dr. HERMANN ARTHUR GUNTHER, a former chairman of the South Middlesex Division of the B.M.A., died at Hampton Wick on Oct. 28 after a brief illness. Born in 1872 in the same house where he died, Dr. Gunther shared with his father, the late Dr. Theodore Gunther, an unbroken family practice for a period of 80 years. During part of his boyhood he was brought up with his cousin, later to become Dr. R. T. Gunther, for many years Fellow and Tutor of Magdalen College, Oxford, and Curator of the Science Museum at Oxford. At an early age he went to University College School, and until he was old enough to make the daily journey to and from Hampton Wick, lived with his uncle, the famous zoologist, Dr. Albert Gunther, F.R.S., at the British Museum. H. A. Gunther studied medicine at University College Hospital, qualifying M.R.C.S., L.R.C.P. in 1896, and taking the M.B.Lond. three years later, after serving as obstetrical assistant at U.C.H., house-physician at the Brompton Hospital, and senior house-surgeon at the Royal Northern Hospital. Then for 40 years he practised at Hampton Wick, finding time in the intervals of a busy professional life to take an active part in the work of the Surrey Archaeological Society and of the Japan Society. Dr. Gunther had a wide knowledge of the history of his native district, and he formed a valuable collection of Netsukes.

Dr. ATHOL RAYMOND MOORE of Camberwell, who died suddenly on Oct. 30, studied medicine at Cambridge and the London Hospital, graduating M.A., M.B., B.Ch. in 1904, after which he served at house-physician and house-surgeon at the Poplar Hospital. Dr. Moore was for many years medical officer to the Newton Institution, surgeon to the L Division of the Metropolitan Police, and Admiralty surgeon for the No. 9 District. During the last war he held a commission as captain R.A.M.C., and received the Medal of the Order of the British Empire for rescue work in connexion with a Zeppelin raid. He joined the British Medical Association soon after qualifying and was a member also of the Medico-Legal Society. In view of his large experience in police work he was appointed a member of the Committee on Tests for Drunkenness set up by the

Council of the B.M.A. in 1926 and also of the Police Surgeon Subcommittee in 1936. A. B. writes: It is perhaps in his capacity as joint hon. secretary of the Metropolitan Police Surgeon Association that Moore will be best remembered by his colleagues and friends. For many years he acted in this capacity, and his sympathy and helpfulness to the individual police surgeon who turned to him in any difficulty were invariably genial and cheerful manner sometimes seemed to temper convictions which he held strongly. But, particularly where the professional rights and interests of his colleagues were concerned, he was persistent in his advocacy. His sense of discipline and his forbearance often determined an urbane exterior which in no way deceived those who knew him best. His loss at this juncture will be especially felt.

The City of York as well as the medical profession of the city has suffered loss by the death of one of the oldest of its practitioners, GEORGE WILFRID GOSTLING, on Nov. 3, at the age of 73. He went to York in 1895 as house-surgeon to the York County Hospital and remained attached to it in various capacities for the rest of his life. He became a member of the honorary staff in 1899, and when he retired from the active staff three years ago he had been senior honorary surgeon and chairman of the Medical Board for many years. He occupied the post of president of the York Medical Society, chairman of the local Division of the B.M.A., chairman of the Local Medical and Panel Committee, to the entire satisfaction of the members of these bodies. Dr. Peter Macdonald writes: A man of great charm, Gostling was not only respected but loved by all who knew him. He had a charitable outlook on things and on people. The writer, who knew him intimately during the whole of his York life and who shared many of his activities, cannot remember ever hearing him say an unkind word to anyone.

News has been received of the death in Peking in June 1943 of Dr. W. H. GRAHAM ASPLAND, physician to the British Legation in that city. Dr. Aspland had an adventurous career. He was born in Toronto in 1868, and qualified in medicine in 1896, proceeding M.D. Toronto in the following year. He was the first doctor to be sent by Sir Wilfred Grenfell's Mission to Labrador. There he met his wife, Miss Ada Carwardine, who had been recommended to Grenfell by Sir Frederick Trevelyan as a nurse, and had gone out from London to organize a small hospital on Battle Harbour Island. On this island, which is icebound for six or seven months of the year, Dr. and Mrs. Aspland worked for some years. Later they went to China as medical missionaries, and at Peking, under Bishop Scott, they founded a mission hospital and ran it with the help of Chinese students. Dr. Aspland, having become fluent in the Chinese language, acquired an interesting practice among high-class Chinese, and from 1905 to 1912 he was professor of obstetrics and gynaecology at the Union Medical College. He did excellent work in China. No enterprise offered too great hardship for him, and during an epidemic of pneumonic plague in Manchuria he went out there, serving under a Chinese doctor. Both he and his wife volunteered, but the authorities would not take women, and so Dr. Aspland went alone. He was in England on leave when war broke out in 1914, and, with his wife, volunteered immediately for service in France. In 1914-15 he was medical officer in charge of a military hospital there and his wife was matron. He held the rank of lieutenant-colonel R.A.M.C. In 1915 they went to Serbia, where he was surgeon-in-chief of the Anglo-Serbian hospital, but in the following year they were taken prisoners by the Austrians. Later they were repatriated from Vienna to England, and Dr. Aspland set forth for fresh adventure in Russia, serving in the Anglo-Russian hospital in Petrograd and later with the field hospital attached to the Imperial Guards. During the summer of 1918 the hospital advanced with the Russian Army through the Pripiet marshes for 80 miles. In 1917 Dr. Aspland went to Armenia and worked for a time with the "Save the Children" Fund. After the Armistice he and Mrs. Aspland returned to Peking, where he served as medical officer to the Legation quarter. When Japan came into the war they were interned in their own house in the Embassy compound. Dr. Aspland received Serbian, Russian, and Chinese decorations, and in 1920 the Cross of the Legion of Honour.

News has been received from India of the death of Dr. JAL PESTONJI PADSHAH, who was holding the post of dean of the G.S. Medical School and King Edward Memorial Hospital in Bombay. Dr. Padshah was born in 1897 in Bombay. He came to this country to study medicine at University College Hospital where he won the Bucknill Scholarship. He graduated M.B. B.S. Lond. in 1920 and proceeded to the M.D. degree in 1922. Dr. Padshah worked in London for nearly ten years before returning to India, and had been a member of the British Medical Association for the past 23 years.

The Services

Cols. A. C. Macrae, V.H.S., and R. V. Martin, C.I.E., V.H.S., M.S., have been appointed Honorary Physicians to the King in recession to Cols. C. A. Wood, M.C., and R. Sweet, D.S.O., M.S. (ret.), respectively.

Cols. (temp.) J. T. McQuat and T. Menzies, R.A.M.C., have been appointed O.B.E. (Military Division) in recognition of gallant and distinguished services in North Africa.

Col. (acting) M. MacEwan, O.B.E., D.F.C., T.D., R.A.M.C., has been awarded the D.S.O. in recognition of gallant and distinguished services in North Africa.

Capt. (temp. Major) M. E. M. Hertford, M.B.E., and Capt. E. W. Aldwell, J. S. Martin, and J. Miedema, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Sicily.

Capt. Christopher St. Johnston, R.A.M.C., was, in September, appointed surgeon to the Commander-in-Chief, India (Gen. Auchinleck), and is now on his personal staff in New Delhi.

Information has been received that Capt. L. V. Macdonald and J. H. A. Simmons, R.A.M.C., who have been prisoners of war, are now in Allied hands.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in North Africa: Brig. (local) L. M. Weddell, Reserve of Officers, late R.A.M.C.; Brig. (local) E. R. Boland, O.B.E.; Cols. (temp.) J. H. Bayley, M.C., F. J. Hallinan; Col. (temp.) G. K. Maurice, D.S.O., M.C., Reserve of Officers; Majors (temp. Lieut.-Cols.) J. C. Alexander, T.D., H. D. Chalke, and S. Heatley; Capt. (temp. Major) (acting Lieut.-Col.) S. S. Chessier; Capt. (temp. Major) F. W. Bunting, R.A.M.C. Jemadar Siddiq Ahmed, I.M.S., has been awarded the M.C. in recognition of gallant and distinguished services in the field.

CASUALTIES IN THE MEDICAL SERVICES

Missing.—Surg. Lieut.-Cmdr. H. de L. N. Davis, R.N.V.R.; Capt. Archibald McLellan, R.A.M.C.

Killed by Accident in New Guinea.—Capt. N. V. McKenna, A.A.M.C.

Prisoners of war.—War Subs. Major J. R. Macdonald; Acting Major P. E. F. Routley, R.A.M.C.

Previously reported missing, now reported killed in action.—Major A. G. Porter, R.A.M.C.

Correction.—The name of Major R. L. Mackay, M.C., R.A.M.C., is incorrectly given among the Repatriated Medical Officers on Nov. 13, p. 627. The correct name is Major R. Mackay, R.A.M.C.

DEATHS IN THE SERVICES

We announced on Nov. 13 the death on active service of Major K. C. Eden, F.R.C.S., R.A.M.C. The Consulting Surgeon of the 8th Army writes: The sad death of Kenneth Eden on Oct. 20 from poliomyelitis robbed the 8th Army of its neurological surgeon. From just after El Alamein he had travelled with his unit through the long desert, into Tripolitania, into Tunisia, into Sicily, into Italy. Because of the paucity of these neurological units, his team was split up into two, the advanced section going to whichever C.C.S. drained the whole fighting line, the other section staying with the most advanced general hospital. Thus patients had their early operation by skilled specialized hands and were passed on to another team devoted to their special care, to be retained for a suitable period. In Africa Eden himself moved into the forward section and gave without stint to the neurologically wounded 8th Army man what he deserved—the best of skill and attention. In the British Army he thus had an unrivalled experience of forward neurological surgery. Eden saw Naples and died: many 8th Army men "saw Eden and lived."

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—1. Patricia M. Lloyd, 2. Josephine M. Lord, 3. Margaret MacGregor, 4. J. J. R. Trencore, R. F. Alexander, B. B. Alhadeff, Janet F. Alkass, D. C. Beatty, W. C. H. Bell, G. Behavin, W. E. J. Bennett, Kathleen N. Berger, T. Bliss, D. H. Broxton, W. St. J. Buckler, R. R. Burn, Joyce M. Butt, R. J. Cairns, F. B. Chasrara, S. L. Clifton, Jean M. Connan, M. Conway, Lorna Cooke, J. G. Cotes, Doris A. Crafter, K. D. Crow, A. G. Davies, F. Deery, Elizabeth B. C. Dickson, M. C. H. Dodson, P. Dransfield, A. G. Eicker, D. H. L. Evans, R. H. J. Fairbairn, A. P. Fletcher, Joan M. L. Galt, S. Gee, T. J. B. Giffen, C. H. Gons, K. L. G. Goldsmith, N. M. Gough, O. B. Griffiths, T. Hawley, J. A. Harary, J. Hart, Sheila Haggard, R. G. Hayward, L. D. Henderson, G. R. F. Hilsen, Geraldine M. Howard, Sheila M. Howarth, J. G. Hunt, J. K. Irvine, Ida T. A. Jackson,

R. F. Jennison, H. B. Kelly, G. Kraft, P. G. Large, I. L. M. Larkin, Ninian Lewis, Una G. Lister, T. H. McCall, N. G. McGuire, E. M. Mackay-Scollay, W. Mackenzie, J. R. M. Miller, R. D. Millward, A. J. Moon, H. C. Moore, J. F. K. Muir, J. Mutch, D. H. D. Paine, Audrey Palmer, Diana G. Paradise, P. R. P. Pearshall, M. G. Philpott, S. Pickford, R. Pilsworth, Betsy J. Poland, C. A. Preenell, Denise A. Pullen, T. A. Quilliam, F. J. Rackow, D. A. C. Reid, J. A. Rider, Dorothy M. Ridout, J. A. Robertson, Joan M. Rochford, R. H. Russell, Elizabeth R. Rutherford, W. H. Smith, P. Solnik, V. H. Sprinzel, R. J. M. Steven, F. G. Strong, G. E. Sutcliffe, P. G. Swann, Bessie P. Thurlow, M. Trosser, Judith M. Waterlow, J. S. Watson, G. F. Wigginsworth, P. R. E. Williams, R. E. Wigram, J. Zimmermann.

1 With Honours. 2 Distinguished in Pathology. 3 Distinguished in Medicine. 4 Distinguished in Surgery. 5 University Medal.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council held on Nov. 11, with Sir Alfred Webb-Johnson, President, in the chair, the Gilbert Blane Medal was presented by the Medical Director-General of the Royal Navy, Surg. Vice-Admiral Sir Sheldon Dudley, to Surg. Comdr. D. P. Gurd, R.N., in the presence of the Council of the College and the President of the Royal College of Physicians.

The following were re-elected Members of the Court of Examiners for a year as from Dec. 9, 1943: Messrs. V. Zachary Cope, C. E. Shattock, E. W. Riches, and W. H. C. Romanis.

Mr. J. Leigh Collis was elected a Hunterian Professor for 1944. The Council approved its Memorandum of Evidence to be given before the Teviot Committee.

Diplomas of Membership were granted to the candidates whose names appear in a report of the meeting of the Royal College of Physicians of London in the *Journal* of Nov. 6 (p. 593), and to Dorothy Willoughby and D. E. R. Kelsey.

Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN PUBLIC HEALTH.—Phyllis M. Burton, Kathleen Fort, Margaret E. Merrick, H. A. Nathan, Lucy M. Sutcliffe.

SOCIETY OF APOTHECARIES OF LONDON

At a quarterly meeting of the Court held on Oct. 26, with Sir Stanley Woodwork, Master, presiding, Dr. J. P. Hedley was reappointed as the Society's representative on the General Medical Council.

The following candidates have satisfied the examiners in the subjects indicated:

PATHOLOGY, BACTERIOLOGY, AND FORENSIC MEDICINE.—A. M. Benson, P. D. Bryant, A. E. Bernstein, D. A. Cox, T. C. McGilmore, G. R. S. Jackson, M. W. Johnston, J. M. Macdonald, J. J. Maskell, J. Middleton, J. C. F. Poole, N. Sachs, J. H. S. Scarlett, C. R. P. Sheen, J. C. Stephens, M. N. Tata, J. Walker, J. K. Wilson, H. M. Wolff.

SURGERY.—A. M. Benson, P. L. Brangwin, R. J. N. Hodges, R. J. C. Hutchinson, J. C. F. Poole, A. M. Rajah, N. Sachs, R. N. Theakston, W. M. Thomas, J. K. Wilson.

MEDICINE.—P. D. Bryant, T. Y. Martin, J. Middleton, J. C. F. Poole, N. Sachs, J. H. S. Scarlett, M. N. Tata, R. N. Theakston, J. M. Thomas, J. K. Wilson.

MIDWIFERY.—S. R. Abrams, A. E. Bernstein, P. L. Brangwin, K. R. J. Coates, T. H. Eustice, E. A. Humphrey, H. R. Mohammed, T. Moss, J. C. F. Poole, N. Sachs, J. K. Sargent, J. K. Wilson, A. M. Wolff.

The Diploma of the Society was granted to G. R. S. Jackson, J. M. Macdonald, J. C. F. Poole, A. M. Rajah, N. Sachs, J. H. S. Scarlett, M. N. Tata, R. N. Theakston, W. M. Thomas, J. K. Wilson.

Medical Notes in Parliament

Ingredients of Packed Foodstuffs

In the House of Commons on Nov. 9 Mr. MABANE stated that a White Paper had been issued explaining the regulations which had been made to enable the Minister of Food to protect the consumer against false and misleading claims of the nutritive quality of foodstuffs. Sections 6 and 8 of the Food and Drugs Act, 1938, and Section 9 of the Sale of Food (Weights and Measures) Act, 1926, were reproduced in the new regulations. The only additional power not previously approved by the House was contained in Regulation 2. This gave power to restrict "the making on advertisements of food of claims or suggestions or the presence in the food of vitamins or minerals." It was unfortunate that a small minority of manufacturers should have been tempted to exploit the national nutritional policy. Reputable food manufacturers, no less than scientists and members of the medical profession, recognized the harm that was being done by misleading advertisements of this nature. It was with the object of bringing them to an end that the new powers had been taken by Order in Council. The enforcement of any specific Orders which might be issued under these powers would be entrusted to local authorities, but they would require, unless it was otherwise provided, to obtain the Minister's consent before proceedings were taken. This would ensure that proceedings were taken against the manufacturer responsible for the false description and not against a large number of retailers through whom the product reached the public.

According to the White Paper it is the intention that in general pre-packed articles of food shall bear a label indicating the name and address of the packer, the common or usual name (if any) of the food, the minimum quantity of food contained in the package, and the common or usual names (but not proportions) of the ingredients. Provision will be made for relaxing these requirements in appropriate cases, and the disclosure of ingredients will not be necessary in the case of foods for which a standard is prescribed under the Regulations. In this way the public will be fully protected as to the quantity of food they are buying or its quality, either by the existence of a standard or by the disclosure of its ingredients. When it is claimed that foods contain vitamins and minerals the label must in future bear a quantitative disclosure of these active ingredients.

Tuberculosis

Mr. AMMON on Nov. 10 opened a debate on tuberculosis. He referred to the rise in incidence since 1938 and desired an indication on post-war planning in regard to housing and medical services so that men should not return from the front to conditions conducive to this disease. There must be an early searching out of cases likely to develop active tuberculosis. Radiography sets could be taken to the factories instead of managements sending workers to distant points. Something could be done by care and training in habits which would restrict the infection. The time had come to draw the line between recoverable cases and those which would not recover, but allowances should be provided for all.

Sir HENRY MORRIS-JONES thought that the black-out had aggravated tuberculosis. In the greater proportion of buildings in this country there was no ventilation during the black-out. Dr. EDITH SUMMERSKILL said that to give allowances only to those patients who were considered curable was contrary to the principles and practice of the medical profession. Sir LAMBERT WARD stated that up to a few weeks ago 17 mass radiography sets had been issued. What were these among 42,000,000 people? Mr. SLOAN contended that hospital accommodation of tuberculosis patients should be part of the general hospital scheme. Colonel H. GUEST asked how voluntary hospitals treating tuberculosis were to associate with State hospitals and hospitals maintained by the rates. Voluntary hospitals were able to carry out research and go in for the high-class surgery which was called for in tuberculosis. The trouble was to know where to send patients when they had undergone the surgical treatment. Mr. MATHERS told of letters from nurses who had contracted this disease in their nursing service and were declared ineligible for any allowance. Apparently there was no compensation for them at all.

Mr. WESTWOOD, replying for the Government, said it was now possible to discover whether a person was liable to contract the disease and possibly to save him from contracting it. The mass radiography was a start. Three sets were to be provided in Scotland. They would be placed in Glasgow, in Edinburgh, and in the county of Lanark. There was difficulty in getting these sets in the midst of war. The shortage of domestic staffs and trained nurses had to be faced. The tuberculosis scheme rested on the recommendations of the Committee on Tuberculosis in Wartime, appointed by the Medical Research Council, at the Government's request, in the autumn of 1941. That committee recommended the controlled use of radiography, and also special financial assistance to induce patients to early treatment. This was an experimental scheme and there would have to be adjustments. The scheme provided relief for patients with pulmonary tuberculosis, and its main purpose was to rehabilitate those who could be rehabilitated. The scheme allowed considerable latitude. It had benefited three out of four cases in Scotland where applications had been made. He hoped incurable or chronic cases would come within the general social security scheme which would apply to those suffering from all diseases.

Precautions against Epidemics

Major LYONS on Nov. 11 inquired what steps had been or were being taken in consultation with the Dominions and Colonies and with the United States of America to ensure that machinery was available to come into complete operation to cope immediately with any world-wide epidemic at the instant of occurrence. Mr. ERNEST BROWN said arrangements for the exchange of epidemiological information were in operation between this country, the Dominions and Colonies, the United States of America, and Allied and neutral countries. The International Sanitary Conventions governing quarantine and other precautions were still being observed by all these countries. Their working had been adapted to wartime conditions and advances in preventive medicine. The risks of epidemics in liberated countries and in the immediate post-war period were

among the matters which would receive closest attention from the United Nations Relief and Rehabilitation Administration.

Diphtheria Immunization.—Mr. VIANT inquired on Nov. 4 the meaning of the Ministry's advertisements in the Press and on the hoardings that immunization protected against diphtheria in view of the statement in the last report of his Department that it had never been claimed that immunization gave complete protection to the individual child. Mr. ERNEST BROWN replied that there was inconsistency between the advertisement and the report. The latter showed that in 1942 the rate of incidence of diphtheria among immunized children was one-fourth or one-fifth of that among those not immunized, and that the unimmunized child was from ten to thirty times as liable to die from diphtheria as the immunized child.

Tuberculosis in Nurses.—Mr. MESSER inquired on Nov. 11 whether any machinery had been established to obtain statistics showing the incidence of tuberculosis among the nursing staffs of tubercular sanatoria separate from those in general hospitals in England and Wales. Mr. BROWN said no such machinery had been established, but he desired to obtain reliable statistical information on the point. He was consulting his Medical Advisory Committee and the Standing Advisory Committee on Tuberculosis as to the scope and form of the inquiries which ought to be made to attain the object.

Notes in Brief

A gas-and-air apparatus has been supplied to every Emergency Maternity Home where a request has been made by the local authority administering the home, and where the staff included a midwife holding the special certificate for the administration of a gas-and-air analgesia.

During the Committee Stage of the Parliament (Elections a Meeting) Bill on Nov. 3 Mr. Peakes for the Government accepted a new clause to permit the appointment of proxies for Service voters at university elections.

The Wage-earners Income Tax Bill passed through Committee the House of Commons on Oct. 20. Resisting a proposal to extend the "pay as you earn" provisions to salaries above £600 a year, Sir John Anderson said he was in favour of extending these at a proper time. He wanted to feel sure he did nothing unfair to professional men assessed under Schedule D. Later Sir John promised to reconsider the scope of the Bill at a later stage.

The Agricultural Research Council has found sufficient time to start field experiments with B.C.G. vaccine for control of bovine tuberculosis. The test must last over five or six years, of which the present year is the first.

Medical News

Owing to the absence of many members on war service the activities of the School Medical Group of the Society of Medical Officers of Health have been suspended for some time past. A meeting has now been called for Friday, Dec. 3, at 2.45 p.m., to be held at the Guildhall, Market Place, Derby, for the election of officers and for a discussion on "The Future of the School Medical Service." The president of the society, Dr. R. H. H. Jolly, will take the chair and all Fellows and members are invited to attend. Those who hope to be present are asked to notify Dr. A. A. E. Newth at 14 Chaucer Street, Nottingham.

At the meeting of the Medical Society for the Study of Venereal Diseases to be held at 11, Chandos Street, Cavendish Square, London, to-day (Saturday, Nov. 27, at 2.30 p.m.) a discussion on "Is a 'No Deal' in Venereal Disease Control Necessary?" will be opened by Dr. I. N. Orpwood Price and Dr. J. A. Burgess. No meeting will be held in December. On Jan. 29 a discussion on "Intensive Arsenotherapy" will be opened by Lieut.-Col. D. M. Pillsbury, Capt. C. J. Courville, and Capt. G. R. Wise, U.S. Army.

The first of a series of clinical and pathological demonstrations will be given in the Royal Salop Infirmary on Dec. 3, at 3.15 p.m., when the subject will be "Disorders of the Blood." The first part will consist of a demonstration of laboratory methods in the diagnosis and control of blood disorders, and the second of a demonstration of cases of the commoner blood disorders. Other meetings will follow, when it is hoped to deal with heart, respiratory, and renal diseases, diseases of the nervous system, and, if possible, all diseases.

The Central Council for Health Education, which is charged by the Ministry of Health with providing material and lectures for the instruction of the public in health matters, urgently needs part-time lecturers. They should be medical men and women who, in their spare time, can give technical instruction simply and in an interesting way to lay audiences. A fee of £1 1s. is paid for each lecture, in addition to third-class travelling and certain out-of-pocket expenses. Further information and enrolment form may be obtained from Dr. Robert Sutherland, Central Council for Health Education, Tavistock House, Tavistock Square, London, W.C.1.

The Secretary of State for the Colonies has appointed a committee, under the chairmanship of Lord Rushcliffe, to examine the action of training, both in this country and over-seas, for nurses to be to serve in Colonial territories, and to make recommendations having regard also to the need in those territories for increased public health activities and for the fostering and development of community welfare. The medical members of the committee are: Mary Blacklock, Dr. W. H. Kaunz, Dr. H. M. C. Macaulay, Dr. A. H. Moody, and Dr. A. G. H. Smart, Medical Adviser to the Secretary of State.

Sir Walter Womersley, Minister of Pensions, and Mr. G. Minson, M.P., Parliamentary Secretary to the Minister of Labour and National Service, recently attended a lecture-demonstration at Leeds to further the plans of the two Ministries for equipping and training limbless persons to enable them to return to industry and to live a life of normal activity. Describing the plans of his Ministry to rehabilitate the limbless, Sir Walter emphasized that the scheme did not affect their pension rights. Dr. R. D. L. Kelham (from Roehampton Hospital) described the great advance that had been made in the training and equipment of the limbless.

The William Osler Medal of the American Association of the History of Medicine has been awarded to George Edward Murphy of the School of Medicine of the University of Pennsylvania for an essay entitled "The Evolution of our Knowledge of Rheumatic Fever." The essay will be published in the *Bulletin of the History of Medicine*.

Christmas cards and calendars will not be so plentiful this year, as the Grenfell Association has a selection available which it is offering as useful in aid of the children of Labrador. There are boxes containing six cards and envelopes at 1s. 6d. and 1s. 9d. and single cards with envelopes at 6d. each, also useful pocket calendars at 3d. Copies will be supplied if postage is sent to the Grenfell Association at 66, Victoria Street, London, S.W.1, or to 21, Bothwell Street, Glasgow, C.2. All who buy will have the double satisfaction of curing cards which, for wartime, are very moderately priced and helping a good cause.

The National Association for the Prevention of Tuberculosis has produced a short sound film about mass radiography. This film will be useful for showing to office and factory staffs, managers, shop stewards, and others before mass radiography examinations are to be made. An advance view of the procedure should help them to form a correct idea of what mass radiography is, and will disarm criticisms from management and workers. It should also show the complicated procedure of passing the subject in and out of the x-ray room, and thus save time. The film is available in 6-mm. and 35-mm. size (non-flam) and lasts for 12 minutes. Apply to Dr. Harley Williams, N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1. The N.A.P.T. cinema unit is available for the showing of health programmes, including the mass radiography film, as engagements permit.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales there were rises in the incidence of acute pneumonia 100, diphtheria 68, and whooping-cough 62, but those of scarlet fever, dysentery, and measles fell by 249, 102, and 32 respectively. The only important local variation in the trend of scarlet fever was a fall of 70 cases in Middlesex. The largest of the local increases in diphtheria was in Yorks West Riding—40. Lancashire showed the biggest rise in acute pneumonia, 43. On account of an outbreak in Birmingham C.B. notifications of whooping-cough in Warwickshire rose by 13. A steep fall occurred in the notifications of dysentery from 148 to 146; during the preceding nine weeks an average of 259 cases had been recorded. In Bedfordshire, which last week had 30 cases, 16 new cases were reported, and 7 from Dorsetshire last week 361. The incidence in London remained at a high level: 43 cases were reported compared with 53 in the previous week. Other centres of infection were Middlesex 17 and Surrey 14.

In Scotland notifications of dysentery rose by 90 cases, of acute pneumonia by 48, diphtheria by 13, and whooping-cough by 11. Kincardine County reported 25 cases of dysentery, and in Edinburgh the incidence of this disease rose from 29 to 85; a small rise also occurred in Glasgow from 8 to 16. In the latter city cases of pneumonia rose by 30.

In Eire scabies—because of its prevalence—has been added to the list of notifiable diseases. In the city of Cork 2,549 persons have been treated in the corporation's clinic since the end of March. 1,076 were adults and 1,473 children.

The Week Ending November 13

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 3,236, whooping-cough 1,902, diphtheria 819, measles 557, acute pneumonia 781, cerebrospinal fever 41, dysentery 158, paratyphoid 4, typhoid 5.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshough Gardens, Edinburgh.

ANY QUESTIONS?

Heat in the Treatment of Shock

Q.—*What is the current teaching on the use of heat for shock? I have been in the habit of telling my first-aid classes that restoring heat to the shocked person is of first importance. I am now told that modern work is showing that the application of heat may even be dangerous. I should therefore like to know the present position with regard to heat in the first-aid treatment of shock and in the treatment of shock in a resuscitation ward.*

A.—The shocked patient is usually cold and, under war conditions, may often be suffering from the effects of exposure. It was formerly regarded as of first importance to apply heat rapidly and vigorously. Modern considerations have led to some well-founded criticism of this line of treatment.

In a normal human subject the application of heat accelerates the circulation, the increase taking place almost entirely through the skin and muscles. It used to be claimed that the improvement in pulse volume following the application of heat in shock was an indication of the benefit achieved. It is understandable that, as the skin of the arms and hands shares in the improvement of the superficial circulation, this observation does not necessarily indicate any change for the better in circulation through vital organs. The shocked patient is suffering from a depletion of the circulating blood volume. It is estimated that when the blood vessels of the skin are dilated by the application of heat, as much as 500 c.cm. of blood may be diverted into this part of the vascular system. When the blood flow through the vital organs is already imperilled by shock, it would appear to be harmful to increase the skin circulation at their expense. Furthermore, the increased heat leads to an increased tissue demand for oxygen, which may create further difficulties in the presence of a depleted circulation. Blalock and Mason in a long series of experiments in dogs produced a standard degree of shock by bleeding and other methods. It was found that the survival time of these animals was considerably prolonged by cooling, while overheating accelerated death.

It would be unwise at the moment to transfer these results unmodified to the human subject and to recommend cooling as a line of treatment. Clinical observations do, however, suggest that over-heating is definitely harmful and should be avoided. If the patient complains of cold he should be given enough cover and warmth for comfort, but overheating should be regarded as undesirable. In the absence of any shivering or other discomfort from cold, it is unlikely that cold does much harm.

"Alarming Effects" of Choline Derivatives

Q.—*In the interesting and chastening article, "Some Therapeutic Fallacies," by Drs. Linnell and Thomson, in the JOURNAL of Nov. 6, the authors, in discussing the treatment of paroxysmal tachycardia, say of acetyl-beta-methylcholine chloride that "its effects in other ways may be alarming." What are these alarming effects, and to what extent do they militate against the use of the choline derivatives—also how should they be counteracted?*

A.—The alarming effects which may be caused are (1) syncope due to sudden great fall in blood pressure, (2) a sense of subnormal oppression or even pain, (3) asthma, especially in an allergic subject, (4) vomiting, (5) diarrhoea or even involuntary defaecation; (6) arrest of the heart has also been described. Atropine in full dosage is an effective antidote and should be kept in readiness in every case in which the drug or an allied choline compound is administered. These drugs should not be used in known allergic subjects, and, if an attack of asthma should be caused, adrenaline chloride should be immediately injected. It may be added that choline compounds should never be given intravenously or with the patient sitting up; and it is always wise to have a bed-pan at hand so that the patient need not raise himself to defaecate.

Spondylitis

Q.—*A patient aged about 30 has been treated since March with wide-field x rays for spondylitis. A radiograph of the lumbar and pelvic areas now shows arrested spondylitis with some decalcification of the thoraco-lumbar vertebrae, fusion of 4th and 5th lumbar vertebrae, sacro-ileitis, and osteo-arthritis of the left hip joint. The patient has not experienced any relief. What is the treatment?*

A.—It is difficult to see how x rays can demonstrate "arrested" spondylitis if decalcification is present and the patient has experienced any relief; it rather suggests wishful thinking. Sedimentation rate would furnish more reliable information. My experience wide-field x-ray therapy has not proved of value in established ankylosing spondylitis and has sometimes been responsible for serious constitutional disturbance; this does not apply to localized deep therapy over a small area at a time. It follows therefore that a second course is not advised. A period of rest in bed with fresh air, heliotherapy or ultra-violet irradiation, cod-liver oil to raise the general resistance, and the wearing subsequently of a well-fitted spinal brace of the Goldthwait or Taylor pattern if work is resumed, is likely to be the most beneficial line of treatment.

Transmission of the Blood Group

Q.—*Does the blood of a newly born baby exhibit the character of one of the blood groups? If not, when do they develop? If they inherited, and do they follow known Mendelian laws?*

A.—Yes. The agglutinogens have been detected as early as the 37th day of foetal life. The reaction at birth is, however, relatively weak and increases in strength during childhood. The agglutinins of the serum are not formed till after birth; any then present derived from the mother. The blood group to which a person belongs is entirely determined by heredity. The mode of inheritance is thoroughly understood. As regards the ordinary blood groups, (A, B, AB, these are determined by which pair of genes is received from the parents. A person receiving two O genes belongs to Group O (universal donors); a person receiving either two A genes or one A and one O belongs to Group A; a person receiving either two B genes or one B and one O to Group B; a person receiving one A gene and one B gene belongs to Group AB. It is now known that not all A genes are the same. A1 produces a 'strong' reaction, a weaker reaction, and A3 a still weaker reaction. A1 and A2 are both common, A3 very rare. The MN series involves quite different agglutinogens. Except in extremely rare instances the corresponding agglutinins do not occur in human serum; they have to be produced by inoculation of rabbits with human red cells. There is only one pair of genes. A person who receives two M genes belongs to Group M; a person who receives two N genes to Group N; a recipient of one M and one N gene belongs to Group MN. The factor which has aroused so much interest in connection with erythroblastosis foetalis (icterus gravis neonatorum) depends on a gene pair, Rhrh. Persons receiving two Rh genes or one Rh and one rh are Rh-positive; persons receiving two rh genes are Rh-negative. The great majority of the babies suffering from the condition erythroblastosis foetalis, the Rh gene being derived from the father. Their mothers may excite the production of the antibody in their blood, so producing the reaction. Altogether nothing in human genetics is better understood than the transmission of the blood group, and it is a story to which further chapters are likely to be added.

Gwathmey's Obstetric Anaesthesia

Q.—*Will you please give me the technical details of obstetric anaesthesia according to Dr. Gwathmey.*

A.—Gwathmey believes that a combination of drugs, each for a specific purpose, produces more than an additive effect, one enhancing the action of the other (synergism). He originally stated that hypodermic injections of magnesium sulphate potentiate the action of small amounts of other analgesic drugs given simultaneously, but he now appears to have abandoned this claim. It is doubtful if the mag. sulph. ever served any useful purpose in the dosage he used. His present technique is as follows: The rectum is washed out with a 5 to 10% sodium bicarbonate solution. The pains become severe the patient is given nembutal gr. 3. The effect of this initial dose of nembutal begins to wear off, the following mixture is run into the rectum: Ether 3 24; quinine alkaloid gr. 20; alcohol n 45; paraldehyde 3 2; olive oil ad 10. This may be repeated after an interval of 24 hours, though it is not often required. The quinine is not given more than twice in the meanwhile further sedation or analgesia is necessary and given further doses of nembutal gr. 1½ when required, and if pains are strong morphine gr. 1/6 is given with this second dose of nembutal, though it is omitted if delivery is expected within 4 hours. Throughout labour the degree of the patient's sufficiency rather than the amount of cervical dilatation is the guide to additional doses of nembutal. At the actual delivery nitrous oxide or oxygen may be used, but not chloroform.

Polyuria

Q.—What is the cause of polyuria and frequency arising in a healthy man of 44? Frequency during the day, every 2 to 3 hours; 0 difficulty, no pain or any other symptoms of disorder: S.G. of ay urine 1000, pale, no albumin or sugar. Occasional single disturbance at night; urine dark, high S.G., onset fairly sudden 1st 2 to 3 months. No apparent disease in any organ, general health excellent, no cardiovascular disease, B.P. 125/80. No thirst, appetite normal.

A.—The degree of polyuria is not stated, and the highest specific gravity of the specimens of urine is not given. If the specific gravity of any one specimen is over 1020 then polyuria is not due to diminished renal function, and if there is a high specific gravity in any specimen, then diabetes insipidus is probably not present. The symptom of polyuria without thirst and with normal appetite suggests that it can only be slight in degree. If the 24-hour volume is less than 1,800 c.cm. the condition is probably frequency without polyuria, and it will be necessary to exclude infection of the urinary tract by microscopical and bacteriological examination of the deposit from a centrifuged specimen of urine. It is assumed that a rectal examination has been made. Other factors which may be considered are alterations in physical or mental habits, diet, or environment. Frequency of micturition is sometimes a symptom associated with anxiety states.

Voluntary Sterilization and the Law

Q.—A woman says to me, "Doctor, I want to be sterilized." Can I do it in the absence of obstetrical indications, or is it illegal?

A.—The sterilization of a woman apart from therapeutic indication is nowhere forbidden by statute law. The Offences against the Person Act, 1861, which was intended to be a complete code of this part of the criminal law, does not mention it. At that date, however, surgical sterilization was not a practical possibility. If a doctor were prosecuted for such an act, the prosecution would therefore have to allege a breach of the common law. This has never yet been done. Judges occasionally create new common-law offences, or, rather, declare for the first time that the act charged is and would always have been an offence. The common law is a body of principles rather than a code, and new ways of offending against those principles may be developed from time to time. It is therefore always open to a judge to rule that a doctor has committed an offence against the common law by rendering (without good medical reason) a woman permanently incapable of bearing a child, for to do so is an injury to the State. Professional ethics has always insisted that medical skill should be confined to medical indications and not directed by social, eugenic, or economic considerations, still less by those of personal convenience. A doctor who disregards his professional code need not be surprised if he soon conflicts with the law. If the sterilizing process was intended to be temporary and could be easily undone, the offence (if it is an offence) would presumably be mitigated. In brief, sterilization without good medical reason is probably illegal, and the doctor would be well advised to leave it alone.

Sulphonamides for "Rheumatism"

Q.—Are there any records of the sulphonamides being used in cases of rheumatoid arthritis and fibrositis, and are they likely to be of use in the infective forms?

A.—Response to sulphonamide treatment is determined not by the nature of a disease but by the identity of the micro-organism responsible. In so far as the conditions named may be caused by either the haemolytic streptococcus or the gonococcus, a good effect may be expected; otherwise probably not. In the great majority of cases an infective origin is incapable of real proof, though it may be suspected; antibacterial treatment is therefore empirical, and has certainly had no consistent success. It has also to be remembered that sulphonamide treatment is generally less effective in chronic infections and those involving less vascular structures than in acute.

Dermatomyositis

Q.—I have a man of 58 under my care at present who has been suffering from dermatomyositis for six months. The left arm and hand are chiefly affected, with typical swelling of the fingers and filling up of the palm, marked limitation of movements, and commencing atrophy of the forearm muscles. He now complains of the chest and right arm, with acute tenderness of the skin and muscles on pressure. Before consulting me a month ago he had had all known treatments for neuritis, arthritis, etc., including gold, vitamin B, (both orally and parenterally), and all forms of physiotherapy, including short-wave, without any relief of pain. A combination of thiosinamine and thyroid aggravated the condition, and codine gr. 1/2 gives no benefit. All forms of heat treatment make the pain worse.

A.—There have been no important advances in the treatment of this chronic condition. One American author suggests that sulph-

anilamide may be helpful, but owing to wartime difficulties the writer has been unable to trace the paper. It is assumed that the diagnosis of dermatomyositis is correct, though the question does not give a very convincing description of the disease. Attempts have been made to demonstrate a relationship between dermatomyositis, myasthenia gravis, and thyrotoxicosis, but even if a connexion exists it does not suggest any line of treatment. From the practical point of view this disease remains obscure, very rare, and of unknown aetiology. There is no specific therapy, and the only thing to do is to push analgesics until relief of pain is achieved.

Haldane's Haemoglobinometer and CO

Q.—We have a Haldane haemoglobinometer in the sick bay; but there is no coal gas laid on. Is there any way we can use this instrument without carbon monoxide? Would a solution of coal gas in distilled water serve the purpose? Is there a large error in the reading if the estimation is carried out without passing coal gas through it?

A.—There is no way of using the Haldane haemoglobinometer without carbon monoxide that is really satisfactory. Carbon monoxide cylinders can be obtained from British Oxygen Company, East Lane, Wembley, Middx., at a price of £2 13s. 6d. per cylinder (17 cu. ft.), and refills can be obtained at a price of £1 6s. 6d. If a fine-adjustment needle is fixed to the cylinder the result is extremely satisfactory. This arrangement is used extensively in the present surveys that are being made of haemoglobin levels. An alternative is to make your own carbon monoxide as described in Peters, J. P., and Van Slyke, D. D., *Quantitative Clinical Chemistry Methods* 1932, 2, 342.

Undescended Testes with Infantile Genitals

Q.—A boy 10 years of age, of a bright appearance and normal intelligence, shows one marked abnormality—namely, under-development of the external generative organs and non-descent of the testes. The genitalia appear like those of an infant and the testes are palpable neither in the scrotum nor along the inguinal canal. There is no tendency to obesity.

A.—This is probably a case of selective failure of the anterior pituitary gonadotrophic function. The correct treatment is the intramuscular injection of chorionic gonadotrophin, 500 rat units twice weekly in alternate months. The prognosis should be somewhat guarded, but there is a high probability that the treatment will be successful.

Breast Lymph and Cancer

Q.—What difference is there, if any, between the lymph in a normal breast and the lymph in a breast with early cancer?

A.—Stasis of lymph is regarded by some as an important precursor of cancer. I cannot recall a demonstration that lymph in a breast with early cancer differs in quality from the lymph in a normal breast.

INCOME TAX

Appointment: Expenses

"N. J." held an appointment in North London and took a house there. He now holds another E.M.S. appointment, south of the Thames. Can he claim an allowance for the following expenses: (a) travelling from his home to the hospital where he works, (b) cost of telephone, which is necessitated by liability to be called out in air raids as casualty officer, (c) cost of books for M.R.C.P. study, and (d) cost of domestic servant in view of his wife's whole-time work under the Ministry of Labour.

* (a) Under the Finance Act, 1942, Sec. 26, an allowance can be claimed up to a maximum of £10 a year if the change in the place of work is (as presumably it is) connected with the present war. (b) Only a proportion according to use, so far as there is a direct connexion with a paid appointment. (c) No—the cost is one of a capital nature. (d) No—the old case of Bowers v. Harding is conclusive on this point.

Proportion of General Expenses

"Y. Z." occupies a large house and garden, which has been attached to the practice for 120 years. Recently the inspector of taxes has refused to continue the allowance for part of the cost of a gardener and claims to reduce the amount allowed for keep of a locum tenens and of a maid employed in the work of the practice. What action should be taken?

* This is one of those questions which depend so much on the facts of the particular case that it is difficult to offer any advice in general terms. The broad principle followed is that the whole expense of the premises should be divided in the ratio in which the premises are in fact used for private or professional purposes. On that basis the claim to an allowance for part of the gardener's wages is weak—it would in strictness probably be confined to the part

spent on keeping the approach to the consulting room in reasonably decent order. As regards the cost of maid's keep, that should be capable of estimation on the basis that it is a fraction of the total cost of the whole establishment. Failing agreement with the inspector of taxes "Y. Z." has the right of appeal either to the local Commissioners of Income Tax or to the Special Commissioners, whose office is in London but who hear appeals locally when "on circuit."

Amount of Tax Payable

F. S.—The facts are sufficiently indicated below:

•• Total income:

	£	s.	d.	£	s.	d.
Dividends	540	0	0			
Property	52	0	0			
Personal Allowance				592	0	0
Taxable Income				140	0	0
Tax at 6s. 6d. on £165				£452	0	0
" 10s. " £287				53	12	6
£452				143	10	0
				£197	2	6

If the total income were £500 only the amount of tax payable would be as follows:

Total Income	500	0	0
Personal Allowance	140	0	0
" Old Age Relief " (one-tenth)	50	0	0
	190	0	0
Tax at 6s. 6d. on £165	53	12	6
" 10s. " £145	72	10	0
£310	£126	2	6
The alternative liability is therefore	126	2	6
plus three-quarters of (£592—£500)=£92	69	0	0
	£195	2	6

As this is less than the £197 2s. 6d. calculated in the ordinary way, £195 2s. 6d. is the true liability.

Allowance for Premiums under Pension Scheme

C. H. inquires why an allowance for premiums paid under a pension insurance scheme is given at the rate of 5s. only, and not at the rate of 7s. 6d., where the total income is between £1,000 and £2,000.

•• The higher rate applies to compulsory payments for deferred annuities to widows, etc.—e.g., where the payment is required by statute or as a condition of employment. Where the payment is made by virtue of a contract the appropriate rate is 5s. (Income Tax Act, 1918, Section 32 (3) (E) as amended).

LETTERS, NOTES, ETC.

Film of First-aid Post during Raids

Drs. L. ARTHUR N. LINE and W. G. ARTHUR (Birmingham) write: A film for the instruction of new or "directed" personnel has been made for the use of the Birmingham casualty services at the first-aid post of which we are in charge. This shows the administration and working of a post during raids, and gives an idea of what is expected of the staff in dealing with typical casualties, and follows the description of such work published by one of us in the *Journal* (Feb. 7, 1942, p. 193). The film runs for about 35 minutes, and though it is "silent" a careful commentary has been written to be spoken when it is shown. While it is by no means perfect and has the limitations of its small-scale production, it is practical and "common-sense" and seems to serve its purpose. As such a film takes many hours of time and trouble to produce we are mentioning it here so that, should other first-aid medical officers outside this area feel the need for such a method of instruction for their posts, further copies may be made for this purpose.

Stilboestrol for Cancer

Dr. WILLIAM MACWEN (Glasgow) writes: I am much interested in recent letters appearing in the *Journal* regarding the use of stilboestrol in carcinoma of the prostate, and I should like to know whether stilboestrol has been used in the treatment of carcinoma of the stomach or of the intestinal tract, and, if so, with what results. Perhaps some of your readers may be able to give information on this matter.

Strychnine for Paralysis

Dr. T. BLANCHARD SELLORS (Berkhamsted) writes: The letter of Dr. J. C. Jones (Oct. 23, p. 534) reminds me that during my tenure of office at R.M.O., St. Mary's Hospital for Children, Plaistow, 1899 and 1900, diphtheria was terribly rife in West Ham and paralytic cases were frequently admitted. Twelve cases of respiratory paralysis—all accompanied by pareses of legs and palate, some of arm, larynx, posterior cervical, facial, or other muscles in addition

—formed the subject-matter of a paper never sent for publication. This has been unearthed and a summary is here appended. An average of the cases shows that a child of 5½ tolerated 1/30 gr. strychnine hydrochlor. hypodermically every four hours for 17 days before exhibiting signs of overdose. The only fatal case began to twitch on the second day and indeed was past hope on admission. One boy of 4, very extensively paralysed, tolerated 1/50 gr. every 4 hours for 27 days. Improvement was rapid in most cases and recovery well on the way before reduction of the dose was necessary. I have no notes of those cases without diaphragmatic palsy, but remember that the good effects of strychnine in these encouraged me to try heavy dosage in severe affections. Such energetic treatment could only be carried out in a hospital under skilled nursing and observation. Absolute rest (a calico band behind the back with loops for the shoulder to ensure recumbence, nas. feeding, etc.) was essential. Whether massive dosage from the start or Dr. Jones's graduation is employed matters little so long as the child is quickly brought under the influence of the drug.

Mycotic Nails

Mr L. N. REECE, F.R.C.S. (Brixham, S. Devon) writes: I was horrified to read under "Any Questions?" (*Journal*, Aug. 14, p. 221) the suggested drastic procedures for the cure of this condition, and haste to advise experiment with a line of treatment which I have been trying out on the cases which have come my way in the past few years. All G.P.s are familiar with the intractable bluish swelling of the nail folds which go on for months or years and discharge or become painful at times, but not all have realized that it is due to a fungus infection. I have made use of the affinity of the aniline dyes for this fungus, and so far have used a 20% wate solution of brilliant green. A weaker solution might be equally effective, and crystal violet would do equally well. My present technique is as follows: In every case of this infection it will be found that the cuticle is to some extent separated from the nail, and on exploring with the eye of a large needle a pocket is found. This pocket is the seat of the infection, and the purpose of treatment is to sterilize it. The eye of the needle is loaded with the solution, and the pocket is flooded and gently rubbed inside over its whole extent. The separation of the cuticle is increased as much as possible without discomfort, to give easy access. If the painting is done gently there should be no more discomfort than a little smarting. If desired, the stained nail fold may be concealed with a small strip of elastoplast. Once the dye has dried, the hand may be washed as usual. After three days the patient returns for a second treatment, when a great improvement will be seen. Almost all pain and swelling will have gone. Painting of the pockets carried out as before, re-separating the cuticle where it is already tending to adhere once more. After this the patient attends weekly intervals for a few weeks and any doubtful spots are repainted. Cure is recognized when there is no swelling, the color is normal, and the cuticle is normally adherent. This treatment is equally effective in those cases of invasion by fungus under the free edge of the nail. So far, in a small series of cases, including one of at least ten years' duration, there have been no failures or complications.

Abdominal Viscera in Thorax of Newborn Infant

Dr. J. B. FRUMIN (Blaenavon, Glam) writes: On June 16 the local midwife reported to me that a normal baby which she had delivered at 11 p.m. the previous night had been found dead 7 hours later. I visited the house and the mother said that she had not slept a night; at 2 a.m. she imagined the baby was cold, but was not unduly alarmed; at 6 a.m. she realized the baby was dead. The midwife told me that the baby had cried lustily and appeared quite normal. At the coroner's request I performed a post-mortem, and found that the abdominal viscera, with the exception of the liver and a portion of the large bowel, were packed in the left side of the thoracic cavity. As I have no idea how rare this abnormality is I report the post-mortem findings in case they may be of interest. The body was that of a male infant about 8 lb. in weight. Face cyanosed, well formed, no external abnormalities. On opening the thorax: left side of thorax was occupied by the stomach, spleen, all the small intestine, most of the large bowel, all enclosed in peritoneal sac; right side of thorax had the heart and lungs. The heart had two well-developed ventricles, but I could find only one large dilated auricle, with no trace of a septum. Right lung expanded; left lung unexpanded and very small. The abdomen contained only the liver, which seemed very large, and the distal end of the large bowel passed straight down from the diaphragm to the rectum. Both kidneys were in normal position.

Correction

In the article on "Employment of the Tuberculous in Industry in the U.S.S.R." (Nov. 20, p. 652), the fourth and fifth lines of the second paragraph should have read, "the People's Commissariat for Health and the Central Council of Trades Unions (which is responsible . . ."

PHYSICS AND THE SURGEON*

BY

H. S. SOUTTAR, C.B.E., D.M., M.Ch., F.R.C.S.

Surgeon to the London Hospital

William Wood Bradshaw, whose memory this lecture honours, was born in 1801 and became a member of our College in 1833. He was a man of unusual enterprise, for in the same year he became a Doctor of Medicine of Erlangen, and his appreciation of education was further shown when in 1844 he matriculated at Oxford as a Gentleman Commoner of New Inn Hall, becoming a Master of Arts three years later. He practised as a doctor in Reading, and in 1854 this College showed its high opinion of his worth by electing him a Fellow as a Member of 20 years' standing. He died in 1866, and his widow endowed a lecture at each of the Royal Colleges "to maintain her husband's name in good repute by associating it with the advancement of the science which he loved, and to testify her gratitude for the happiness which she owed to him." I feel that William Bradshaw was a man we should all like to have known and whose memory we gladly honour. He was an ornament to the College, and I am grateful to our President for the opportunity he has given me of following his own memorable Bradshaw Lecture of 1940.

It has been customary to choose as a subject for the Bradshaw Lecture some aspect of surgery which has interested the speaker for much of his life, which is of general interest to his colleagues in the art of surgery, and which is not without interest to the layman. In choosing as my subject Physics in Relation to Surgery I have entirely satisfied the first condition, and I hope to satisfy the other two. It is of course a vast subject, and I can only touch on a few of its fields; of these I have chosen Force, Heat, and Radiation as branches of physics which affect the surgeon most closely and which he is constantly turning to his own use. But even in these I must limit myself to a few problems with which I have met in surgical work and upon which some knowledge of physical principles has thrown light, sometimes revealing important features that would otherwise have been missed.

Force and Movement

Two of the most important subjects considered in physics are Force and Movement, and of these we have endless examples in the human body. The movement, of course, occurs at the joints, and the force is exerted by the muscles; but few of us are aware of the forces which the muscles can exert, or appreciate the exquisite precision of the mechanism by which the movements are controlled. The best examples are always obtained from one's own experience, and I cannot choose a better illustration than one from an exercise of which in years gone by I had ample experience—the pulling of an oar. From our standpoint it is a very simple action and lends itself to accurate measurement, though from the oarsman's point of view it is anything but simple. Seated on a sliding seat and driving with his full power from the stretcher, he can exert a drive

of 400 lb. weight. As his seat moves freely it follows that through each of his legs he exerts a driving force of 200 lb. Let us see how this is accomplished.

Although apparently so simple, the movements involved are by no means simple and the forces employed are exceedingly complex. The most important movement, however, is the straightening of the knee, and the muscle effecting this is the quadriceps extensor. Now in my own case, while the slide travels 18 inches my patella travels only 3 inches, or one-sixth of the track of the slide, and therefore if the quadriceps alone did the whole of the work the force exerted by the quadriceps on the patella would be six times the driving force exerted by the leg, or 1,200 lb. This is an exaggeration, as other muscles act indirectly, and noticeably the gluteus maximus in extending the hip; but I should be well within the mark in saying that my quadriceps alone can exert a force of 600 lb., and that the whole of my thigh muscles acting together can exert a total force of half a ton. Moreover, these great forces have to be exerted with the utmost delicacy, for the watermanship which controls the balance of a racing boat depends upon differences in the pressure of the toes measured in ounces.

Now the modern treatment of a fractured femur is to reduce the fracture to an accurate position by traction, and it is usually found that a force of 15 lb. is quite sufficient. How do you account for such a ridiculous disparity? To talk about tiring out the muscles is absurd, for the effect on the patient's comfort is immediate. What really happens is that the irritation arising from the fracture is checked, the reflex which produces spasm of the muscles is broken, the muscles relax, and it is on the relaxed muscles that traction is exerted. It is of importance that this point should be remembered when the powerful methods of modern skeletal traction are employed, and its neglect has often resulted in failure of a simple fracture to unite.

In order that such a small force should be effective it is essential that the limb should be slung quite freely so as to avoid friction, and if this is done the traction force has a secondary result, to which it is worth while to call your attention. There must, of course, be some counter-pull to prevent the patient being pulled out of bed, and this is most easily obtained by raising the foot of the bed. But you will see at once that this counter-pull acts on the centre of the pelvis, while the traction pull passes through the hip. This side of the pelvis is thus pulled down so that the pelvis lies obliquely and the leg is effectively abducted at the hip. In the case of a fractured femur this is of no importance, but in many conditions of the hip-joint abduction is the essential point in treatment. You might imagine that this would easily be obtained by swinging the leg out; but this is by no means the case, as the pelvis may swing with it. Traction in the line of the leg is the correct physical method of obtaining abduction; but this simple fact is not generally appreciated, and the so-called abduction splint is still too often seen, even—low be it spoken—in the wards of orthopaedic surgeons. Moreover, traction in the line of the femur can abolish pressure

*The Bradshaw Lecture, given before the Royal College of Surgeons of England on Nov. 11, 1943.

on the hip-joint, and in the case of inflammation in the joint this may effect the immediate abolition of reflex spasm and the dramatic relief of the patient. Direct attempts at abduction will increase the pressure and, by increasing spasm, make abduction impossible.

One of the most interesting muscles in the body from the physical standpoint is the biceps muscle of the arm. As its name implies, it arises by two heads from the scapula; it lies in front of the humerus, to which it has no attachment, and is inserted into the back of a tubercle on the inner side of the radius. Its action is thus a very complex one, and the provision of a single muscle for this very complex movement is a measure of its importance. It rotates the forearm outwards, it flexes the elbow, and it flexes the shoulder; and it thus achieves the most important of all human movements, for it enables us to bring food to our mouths.

But for the moment I would direct attention solely to one element of this movement—the rotation of the forearm. The very powerful movement of supination is effected by two muscles, the biceps and the supinator brevis, both acting at what we term great mechanical disadvantage and the biceps taking the larger share. By holding a weight at the end of a rod and raising it by rotating the forearm it is easy to measure the force involved and to show that the biceps tendon, which is no bigger than a shoelace, can easily support a tension of at least 100 lb. weight.

But the biceps does far more than merely provide a powerful force, for by its nervous connexions it measures the amount of force and adjusts it to requirements, and at the same time it acts as a delicate feeling piece, defining exactly the degree of its contraction and giving most precise information as to the position of the limb. How superbly the muscles perform this function can be seen in the facility with which a pianist can strike a distant note with absolute certainty and without the aid of vision.

The position of the hand and arm produced by contraction of the biceps, supination, and flexion of the elbow and shoulder is of particular interest, as it is that adopted by the violinist and the fencer, and far from being an abnormal position, it is that in which the fingers and the whole limb are under the most perfect control. I do not suppose that it has ever occurred to a violinist that it is to his biceps that he owes the possibility of maintaining the position of his left hand. Still less would it occur to him that the peculiar action of the right hand in drawing the bow, described as raising the wrist, is essentially based on a rotation of the forearm, again controlled by the biceps. Rotation of the forearm is indeed a movement of countless uses, and one over which it is possible to develop the most exquisite control.

Another muscle whose mechanism has always fascinated me is the opponens of the thumb. This little muscle is capable of exerting great force, and with the adductor pollicis forms the basis of a powerful grip. But the beauty of its action consists in the rotation which it gives to the thumb so that this may face the object grasped. Whatever the size of the object—a large ball, a ring, a pencil—it will be found that the pulp of the thumb faces the object and ensures a powerful and yet most delicate grasp. It is one of the most perfect examples of adaptation to function in the human body.

Force and the Skull

So far we have considered the forces exerted by the human body. Let us now consider the forces it is capable of resisting, and as an example let us consider the effects of a blow on the head. If a man were struck on the head by a stone weighing 1 lb. and falling a distance of 9 ft., he would probably have some degree of concussion, although his skull might not be broken. Let us consider the forces involved. The stone falling 9 ft. reaches a velocity of 24 ft. per second, and as it weighs 1 lb. it has acquired 288 foot-second units of energy. If it deforms the skull one-quarter of an inch, which is about the possible limit, it means that the resisting force has destroyed this amount of energy in $1/48$ of a foot, and the average force must therefore be 48×288 units of force, or 432 lb. weight. If this be distributed over an area of the skull $2\frac{1}{2}$ in. in diameter it would mean a local pressure of 86 lb. to the square inch.

Now, the skull is for all practical purposes filled by an incompressible fluid, which for such sudden forces has to escape. Any deformation will be resisted by a rise in intracranial pressure, and the effect of this will be enormously greater than any resistance offered by the comparatively elastic skull. Thus the rise in intracranial pressure in the case we have described will be at least in the order of 80 lb. to the square inch. Such a pressure, even though it lasts only for a fraction of a second, must force every drop of blood from the capillaries and leave the brain completely anaemic, with the clinical result of a complete and instantaneous paralysis. Surely this provides a complete justification of Trotter's theory that the phenomena of concussion are the result of sudden anaemia resulting from the rise in intracranial pressure. So far as I am aware he never actually calculated the pressure, but the surmise is an example of the penetration of his intellect. No more acute brain than that of Wilfred Trotter has ever adorned the College—like a diamond in the keenness of its penetration, in its crystal clearness, and in the sparkling brilliance of its humour, as he himself was like a diamond in the flawless perfection of his character.

My attention was first directed, many years ago, to the problem of intracranial pressure by a curious case which came under my care at the London Hospital. A child of 3 years had been knocked down by a light cart, the wheel of which passed over her head. She was unconscious and had a large and very dirty lacerated wound of the scalp above and behind the right ear. I cleaned the wound up as well as I could and in doing so noticed a fine crack running vertically through the centre of the temporal region. The condition of the child precluded any further disturbance, and indeed I was astonished two days later to find that she was fully conscious and in very fair condition. Then, however, she went back, and at the end of four days from the injury was comatose, with clear sign of intracranial pressure. Expecting to find an intracranial haemorrhage, I trephined and discovered beneath the hairlike crack not blood but an extradural disk of hard mud, 2 in. in diameter and $1/4$ in. thick in the centre. I removed the mud and left the skull widely open. To my amazement the child made an uninterrupted recovery.

Now, the considerable mass of mud can only have got in through the crack, and as the force applied was but momentary the crack must have opened widely. If one may estimate the momentary force as 250 lb. weight, this would be supported only by the pressure within the skull, for the skull of a child is far too fragile to offer appreciable resistance to such violence. If, further, we regard the child's skull as a sphere 5 in. in diameter and imagine it to have been flattened by the compression of the wheel over an area $2\frac{1}{2}$ in. in diameter, as would seem a reasonable approximation, we find that the force of 250 lb. weight must have been supported on an area of 5 sq. in., so that the pressure within the skull must have been 50 lb. to the square inch. Now the central cross-section of a sphere 5 in. in diameter is just 20 sq. in., and as the internal pressure, although momentary, is exerted equally in all directions this means a disruptive force of 1,000 lb., or nearly half a ton, so that the wide opening of the crack is fully explained. That such forces must produce anaemia is obvious: that the brain should recover shows how little even the most delicate cells are affected by mere pressure and that in every case its most important effect is to deprive them of their blood supply.

The Absorption of Heat

A very interesting problem in physiological physics, and on with practical results of the first importance, is introduced by the application of heat to the surface of the body. As a simple example let us consider what happens if the forearm is placed in a tank of flowing water at 110° F. If the forearm were a mere mass of inert flesh its temperature would rapidly rise to that of the water; but that this does not occur is shown by a very simple experiment which I owe to Sir Thomas Lewis. If while the arm is immersed in the bath its circulation is checked, in a few seconds the feeling of comfortable warmth gives place to intolerable pain, for the deep layers of the skin are too sensitive to stand such temperature. With an intact circulation the vessels of the skin rapidly dilate and the heat is carried off by the blood stream.

so that the temperature within the limb is prevented from rising to a painful level. The temperature in the deep tissues does, however, rise to a certain degree, and in response to this the vessels dilate and the blood flow increases. This necessarily results in increased metabolism and an internal production of heat in the limb.

An elaborate protective mechanism is thus brought into play, depending for its effectiveness upon an intact circulation, and in this the skin plays a predominant part. The skin protects the deep tissues in two ways. When it is cold and avascular it forms an efficient defence against the loss of heat, without which one could survive in a cold sea only for a very short time. When it is warm its vascularity increases enormously, so that the blood flow may be a hundred times as great, and it now protects the deep structures by the amount of heat it can carry away in the blood stream.

If, however, owing to local pressure or some defect in circulation the flow of blood in the skin is diminished, this protective mechanism breaks down and the temperature of the skin itself, or even of the deeper structures, may rise to such a point that coagulation and local death of the tissues occur. This is undoubtedly the explanation of many of the hot-water-bottle burns, especially under anaesthesia and in patients with defective circulation. It is the explanation also of necrosis arising in another circumstance, in which the connexion is far less obvious.

Endothermy is one of the most valuable gifts of physics to surgery, and with reasonable precautions and in skilled hands it would seem to be perfectly safe. It consists in the passage through the body of a high-tension current which oscillates to the order of a million times a second—so rapidly, in fact, that none of the chemical effects of electricity occur in the tissues. The current, however, is comparatively large and may reach as much as three amperes, so that a great amount of heat is produced by the resistance of the tissues; and it is characteristic of endothermy that, as the name implies, the heat is produced in the tissues. If, for example, the two poles of the apparatus are held in the hands the only sensation is one of peculiar warmth inside the wrists and spreading up the arms.

Now, provided that the heat is carried off by the circulation so that the local rise of temperature is not excessive no harm results. If, however, this condition is not satisfied terrible disasters may occur. It is quite common to place the so-called indifferent pole under the sacrum, and unless a large soft pad is used it is obvious that the pressure on the thin skin in this region may render the skin avascular, so that its temperature may rise to a dangerous point. But this is not all. The sacrum itself has a poor blood supply and is not very sensitive, so that even in a conscious patient its temperature may rise dangerously. I know of two cases in which it underwent total necrosis. The risk of such a disaster is very real, and the indifferent endothermy pole should never be placed in this position. In fact, wherever it is applied care must be taken that the blood supply of the tissues is adequate and not obliterated by pressure; for unless this condition is satisfied extensive necrosis of the skin may occur.

The increased metabolism which arises from the heating of the tissues introduces considerations which show how dangerous it is to regard the body as a mere piece of physical apparatus, and this is especially the case where there is a defect in the circulation. If heat is applied to a limb in which the circulation is so defective that it cannot respond to the demands made upon it, gangrene may be precipitated. If, on the other hand, heat is applied to some other part of the body no harm can be done, since heat can only be conveyed to the damaged limb by its circulation, and increase in this can only be beneficial. In a case, therefore, of incipient gangrene heat may be applied to any part of the body other than the affected limb, where only the loss of heat should be prevented.

Similar considerations apply in certain cases of shock: for if the body is heated when the amount of circulating blood is inadequate the resulting vasodilatation and increased metabolism may actually result in a further lowering of the blood pressure, with even fatal results. The supply of heat is justified only when it has been established that there is an adequate amount of blood in active circulation.

Radiation

I would turn now to another branch of physics of recent development, the implications of which we are only just beginning to realize. Radiation is of course one of the oldest of physical studies, for it is radiation which brings to us the heat, energy, and light of the sun; but it would not be too much to say that its developments in the last 25 years have revolutionized our lives. To it we owe the wireless waves which allow us to speak and to listen across the world. X rays are only one of its forms, and it is to radiation alone that radium owes its power.

The radiation of which I am speaking consists of ether waves transmitting energy across space at a uniform velocity of 186,000 miles a second, so that the light of the sun takes just 8½ minutes to reach us across 93 million miles of space. No matter what the wave-length of ether waves their velocity is unaltered, but the physical effect of the radiation depends on the wave-length. In order to appreciate the vast range of wave-lengths at our disposal, one may make a diagram in which the whole range of 60 octaves which we use is illustrated graphically by objects of similar dimensions. At one end of the scale we have the very long waves, each of which might reach from here to Aberdeen; and then we have the ordinary wireless waves ranging from 2,000 metres to as little as 10 metres—a range of about 8 octaves. Heat waves come next, occupying a short region of wave-lengths from one-hundredth to one-thousandth of a millimetre; and then comes the single octave which gives us light. For this octave alone are we provided with any sense organ capable of appreciating the vibrating energy by which all space around us and within us is filled. To this octave we owe our perception of the beauty of form and colour by which we are surrounded, and without it the blue sky, the rolling clouds, the green fields, and the infinite variety of Nature's shades would for us no longer exist. One wonders what the other octaves might reveal could we but perceive them.

Beyond the light octave come the ultra-violet rays, and, far beyond these, x rays and the gamma rays of radium, the last so short that one hundred thousand would be required to equal one wave of yellow light.

Now, it is a fundamental law of radiation, although it was discovered by Planck but a few years ago, that it can only exist in certain units of energy and that the energy in each unit is inversely proportional to the wave-length: thus the unit of energy for hard gamma rays is one hundred times that of ordinary deep x rays and a hundred thousand times that of yellow light. It is to this that such rays owe their penetrating power and their effects upon the tissues. The shorter the wave-length the greater the energy, and in exact proportion; so that to compare the unit of energy from radium with the unit of visible light is to compare a 12-in. shell in full flight with a pellet from an air-gun.

X rays and the gamma rays of radium have now taken their place as established instruments of surgical technique, but to understand their use it is essential to know something of their origin and nature. Both arise within the atom, but from very different sources.

In the modern view all matter is built up of atoms, and each atom of any one substance has an identical structure, whilst all atoms are variations and elaborations of the same general pattern. Each atom consists essentially of a nucleus round which circulate a number of electrons, themselves minute and identical particles of negative electricity. Hydrogen is the simplest of all atoms, consisting only of a nucleus and one electron. Helium has a larger nucleus and two electrons, and the atoms of the elements gradually increase in size until we reach uranium, with a vastly complex nucleus and a cloud of 92 electrons flying around it. Radium itself is, nearly as complex with 88 electrons in its service.

Radiation arises from disturbance of the electrons in their orbits and from their attempt to regain their normal positions. As one might expect, the possible radiations of any given element are strictly limited, and to this it owes its spectrum. Every element has its own peculiar spectrum or group of lines, each of which represents one wave-length of radiation, the whole forming the signature of the element by which its

presence can be detected with absolute certainty even in the furthest star. Various forms of disturbance can give rise to radiation, and the commonest is, of course, heat, the source of most of the spectra with which we are familiar.

There is, however, a much more powerful way of arousing the electrons to radiate, and that is by hurling at the atom a stream of electrons driven by strong electric forces, and it is in this way that x rays are produced. The result is a radiation of short wave-length, perhaps one ten-thousandth of that of light and of corresponding energy. To obtain such results a modern x-ray plant may require half a million volts—a really terrific force comparable to that of a flash of lightning. It is a wonderful achievement that we are able not only to produce such vast physical forces but to control them and to bend them to our service.

The gamma rays of radium arise also from a disturbance of the electron field of the atom, but this disturbance is produced not by any outside influence but by an explosion of the nucleus of the atom itself. For reasons of which we are entirely ignorant the nuclei of the atoms of radium explode at regular intervals at an absolutely uniform rate of roughly one atom in a million per day. As a result, another substance—the gas radon—is formed, the atoms of which again explode but at much shorter intervals, and this process is repeated until there is left only an inert particle of lead. The whole process is described as “decay,” and it is not too much to say that the discovery of the decay of radium by Becquerel revolutionized all our conceptions of matter.

These successive explosions of the nucleus in the process of decay produce a violent disturbance of the electron field of the atom, and as a result a radiation is produced of very short wave-length and enormous energy. The radiation is thus identical in kind with that of x rays, but of x rays produced by an energy of two million volts. Moreover, such x rays would require a huge engineering plant for their production, while the gamma rays are given off in a continuous stream by the most minute particle of radium.

Now it has been found that such radiation of short wave-length and great energy had a profound effect upon the tissues, and especially upon cellular growth. Where the cells are dividing rapidly they may be completely destroyed, and it is this property which gives these rays their peculiar value in the treatment of malignant growths. In such growths the cells are always dividing at a rate many times, sometimes thousands of times, more rapid than that of normal cells, and it is just this rapid division which marks them as vulnerable to x rays and gamma rays.

But it must not be imagined that the normal tissues are immune. They are profoundly affected, and the greatest skill is required to destroy a growth by radiation without doing irreparable damage to the tissues in which it lies. Some sacrifice is unavoidable, but it should be only such as can in time be remedied by the natural processes of repair.

Of the exact mechanism by which the radiation produces its effect upon the cell we know almost nothing; but it must certainly be atomic, and the primary effect must be the ionization of certain atoms and a consequent rise in their chemical activity. Some substance is thus produced which is toxic to the cell, or perhaps some substance is destroyed which is essential to its normal growth. It would seem to be upon the chromosomes and upon the reproductive mechanism of the cell that the effect is most severe, for it can be shown that the cells which survive and continue to reproduce are themselves deformed and transmit their defects to succeeding generations.

It is evident that in radiation we possess a powerful but very dangerous weapon, for though it may destroy a malignant growth it may do incalculable damage to the tissues which remain. Moreover, if the growth is not completely destroyed and reappears it will now spread in the tissues damaged by radiation, with annihilating effect. I believe that in radiation we have one of the greatest weapons of surgical progress; but it is indeed a weapon and not a tool, and only those who are prepared to devote their lives to its study have any right to use it except in very limited fields or with the close co-operation of those who understand its dangers as well as its powers.

Conclusion

I have ranged over a very wide field and yet I feel that I have only touched the fringes of my subject. I hope that I have convinced you that there are many points at which the work of the surgeon enters the field of physics and that toward the solution of many of the problems of surgery the physicist could give invaluable help. I trust that the future may see a fuller collaboration between two branches of science which at first seem to have little in common and that each may gain from the experience which the other brings.

THE HUMAN RESPONSE TO FLYING STRESS

BY

C. P. SYMONDS, D.M., F.R.C.P.

Air Commodore, R.A.F.V.R.

LECTURE II: THE FOUNDATIONS OF CONFIDENCE

Fearlessness

In this lecture I shall consider the nature of fearlessness, which I mean a state of mind in which fear is absent under circumstances which would naturally be expected to arouse that emotion. I should make it clear at the outset that I distinguish fearlessness from courage. The latter is a state of mind in which fear is present, but is endured for the sake of attaining an object. Fearlessness, as the word implies, is a state in which there is no need for courage because fear does not exist. Fearlessness in relation to a particular stimulus pattern may be primary—meaning that no fear response has ever occurred; or secondary—meaning that the fear response was at one time present but has since been lost. Reverting to what has been said of the origin and growth of fear reactions in children, we may postulate causes for fearlessness of the first kind. First, certain trigger responses may be lacking owing to constitutional variation. Secondly, the process by which the original trigger responses normally develop, that they respond to a wider range of stimulus patterns, may be interfered with. This process may be called learning. In Pavlov's (1927) terms the development of conditioned responses, and may be interfered with in a number of ways. Broadly speaking in terms of conditioned response, we may distinguish between processes which depend upon variations in the efficiency of the cerebral cortex as analyser and those which result from variations in experience and training. For either of these reasons there may be failure to acquire the fear reactions which most people do acquire as the result of conditioning.

Thus there is a kind of fearlessness which is associated with lack of intelligence or imagination. Fearlessness of this origin may be a source of strength in time of danger, but carries with it a source of weakness. The same defect of brain or mind which prevents the acquisition of fear by conditioning or experience prevents the inhibition of fear by conditioning or experience. Thus the stupid man is fearless in the presence of remote or complex danger, but in the presence of immediate obtrusive dangers he is apt to be more overcome by fear for the moment than others of greater intelligence. Nevertheless the man whose lack of imagination prevents anticipatory fear is thereby saved much stress.

That training and experience, or lack of experience, may affect the range of fear reactions is theoretically obvious and is commonly observed. The factors involved are numerous and complex. Parental example and influence are clearly of great importance, and begin to operate so early that it must be very difficult to trace their origins. It is possible that an inhibitory process may in some instances anticipate the development of a positive conditioned response, or even, as Valentine (1942) suggests, that inhibition may be so well established on some other foundation that an unconditioned fear response destined

* Based upon the Dunham Lectures at Harvard University, March 1943, and the Croonian Lectures before the Royal College of Physicians of London, May, 1943.

to mature late never appears. The fearlessness of inexperience, due simply to lack of opportunity for the development of the ordinary range of conditioned fear responses, may be viewed separately. It is commonly observed in children, but comparatively rarely in adults, except under novel circumstances such as those of war. Then the noise of the approaching shell may leave the novice unmoved while at once exciting fear in the man who is aware from experience of its meaning. Unawareness of danger may also occur (even in the experienced person) from narrowing of the field of consciousness. A man may be so preoccupied with task or train of thought that there is no room for the idea of danger. The direction of such preoccupation has probably an emotional bias with inhibitory effect.

Apart from those varieties of fearlessness which depend upon the number and specificity of innate tendencies and the capacity and opportunity for acquiring conditioned reactions, both of a positive and of an inhibitory kind, it seems not impossible that in some individuals—to borrow a physiological expression—the threshold for fear is relatively high, as an innate quality. Such innate variation in the threshold of the fear response would be comparable with the variation in the affective response to painful stimuli observed by clinicians. The individual who is relatively insensitive to fear—using the word “insensitive” with this restricted meaning—may be fearless under circumstances which would be expected to arouse fear in others, not for lack of intelligence, imagination, experience, or attention, but because the stimulus, whatever other effects it produces, fails to arouse the affective response. Such a man might at the extreme react to danger with flight but not feel fear, for the same kind of reason as a man insensitive to pain might throw away a match which he saw was burning his fingers without feeling pain.

Continuing with the same metaphor, fearlessness may be due to a low threshold for some affective response which can inhibit fear. Most fear-evoking situations are complex, and contain stimuli capable of evoking affects other than fear. Just as there are persons who are by nature especially sensitive to the evocation of fear, there are those in whom other kinds of affective response are relatively easily aroused, more intense, and of longer duration. Anger provides a good example, for many situations which are capable of provoking fear are also capable of provoking anger. If a person with a low threshold or anger be exposed to such a situation he may feel anger when another person would feel fear. Fear in these circumstances is inhibited.

Inhibition as a Basis for Fearlessness

I have already used the word “inhibition” more than once in connexion with the absence of fear, and it becomes necessary at this juncture to discuss its meaning, for I believe that inhibition, besides playing some part in primary fearlessness, is the basis of all secondary fearlessness, the subject which I am next going to consider. The neurophysiological concept of inhibition is best illustrated from the spinal or decerebrate animal. Here for a given muscle an afferent nerve may be found whose stimulation causes reflex contraction; another, whose stimulation diminishes or abolishes contraction if already present. Concurrent stimulation of excitatory afferent and inhibitory afferent reveals gradation of effect according to the intensity of the stimuli. A strong inhibitory stimulus will abolish, a weaker inhibitory stimulus will only diminish, the effect of the same excitatory stimulus. But, as Sherrington (1925) has said, there is more to be observed than this:

“Stimulation of the inhibitory afferent when the excitatory reflex is not in operation may seem to produce no central effect. That this absence of central effect is, however, only semblance can be shown in several ways. Thus precurent brief stimulation of the inhibitory afferent will lengthen the latency and diminish the result of a closely following stimulus of the excitatory afferent. Again, stimulation of the inhibitory afferent begun precurrently and continued concurrently with stimulation of the excitatory afferent can prevent altogether or diminish the reflex result of the latter.”

The inhibitory effect under these conditions is not manifested directly, but indirectly by the absence of an expected contraction or an expected degree of contraction.

Contraction of a skeletal muscle depends upon the excitation of the motoneurone, and reflex contraction upon whether the

flow of impulses peripherally aroused reaches the motoneurone to excite it. Sherrington conceives an interplay of central excitatory and central inhibitory activities at a point of confluence which he describes as “upstream” of the motoneurone. Whether the motoneurone is set into activity or not depends upon the balance here between central excitatory and central inhibitory states. The central inhibitory state is as much a

Diagram to illustrate the balance between excitation and inhibition in the reflex arc. C.E.S.=central excitatory state; C.I.S.=central inhibitory state.

positive phenomenon as the central excitatory state, and must itself be excited by appropriate impulses from without. When thus excited it safeguards the motoneurone partially or wholly from excitation. It seems that the hypotheses of central nervous function at the reflex level which I have outlined may be applied with profit and without any great stretch of the imagination to physiological processes underlying the excitation of affect. We may suppose a central inhibitory state for a given affect (for example, fear), maintained by appropriate afferent stimuli, which would not be manifest at all except when stimulation of the excitatory afferent for this affect occurred. Then the inhibitory state would be revealed either by the absence of any affective response or by a response of unexpectedly small degree. We should then observe what we have described as fearlessness—the absence or relative absence of fear in relation to situations which might be expected to cause it.

The analogy of inhibition in a physiological sense has previously been employed by Rivers (1924) with particular reference to fear or “wind up” in air-crews during the last war. Rivers identified inhibition with the psychopathological concept of repression, and assumed that when a reaction to danger was unaccompanied by fear this emotion was present “in the unconscious.” It is difficult to accept this concept, for, as McCurdy (1925) remarks, “repressed” or “unconscious” affect is a contradiction in terms. An affect as such cannot have any existence unless it is conscious, because it is something that a person feels: it does not exist until it is felt. The view which I have taken differs in supposing inhibition to occur “upstream” of the point of affective response. The central inhibitory state is revealed by the absence of affect, as in the motor system it is revealed by the absence of contraction in a given muscle. The affect might be said to be potentially present in so far as nervous impulses have been generated which would have excited the affect if they had not been blocked short—“upstream” of—the central point of excitation. But there has been no experience of affect, no registration of affect in “the unconscious.”

There are two further points of reference for this analogy. An excitatory impulse if blocked by inhibition has no apparent effect, but this again is only semblance. It will have added an increment of excitation to the central excitatory state, thus cancelling an equal amount of the central inhibitory state. The balance in favour of inhibition is thus temporarily diminished, and a further excitatory impulse arriving during this time will meet with less resistance. This is in accord with the observation, which seems from introspective account to be true, that a frightening experience which does not in itself excite fear may have the result that for the time being fear is more easily excited by another stimulus of the same kind. There is, in fact, at the physiological or subconscious level central summation. The second point is that inhibition may provide one explanation for the absence of fear at the time of danger and its appearance later when the danger is past. The

inhibitory forces may be various—anger, sense of duty, self-regard, or what Rivers called manipulative activity. These contribute to a central inhibitory state which occludes fear for the time being. As the situation develops the strength of these inhibiting stimuli becomes less. The occasion for anger is past, duty and self-regard are satisfied, the central balance alters, inhibition is weakened, and fear if still excited appears.

This attempt to describe certain aspects of fearlessness in physiological language is made not without realization of the dangers of over-simplification. Its excuse must be the desire to be explicit in applying the word "inhibition" to affective processes.

Pavlov's Observations applied to Fearlessness

I have already referred to the observations of Pavlov (1927) on the development of conditioned responses in connexion with the growth of fear. His observations on inhibition are of equal value in understanding the growth of fearlessness. He showed that by various means it was possible, after a conditioned response had been established, to diminish or prevent the expected flow of saliva. The main variations of Pavlov's inhibitory responses, as will be remembered, are as follows. If a positive conditioned reflex (salivation) is established by the association of a stimulus—for example, the sound of a bell, with subsequent feeding—and then the bell is sounded on several occasions without feeding, salivation ceases to occur. The conditioned response is then said to have suffered extinction. The extinction of conditioned fear is a matter of common observation. A previously indifferent stimulus becomes by association a danger signal and by itself produces fear. One may take as one example the sound of a siren which has been followed by the fall of bombs. A conditioned fear response has now been established. Now, if the same stimulus is frequently repeated without subsequent bombing it ceases eventually to elicit fear. The conditioned fear response has been extinguished.

A second variety, called conditioned inhibition, is induced thus. A well-established conditioned stimulus is combined with a new (indifferent) stimulus, and the combination is repeated without subsequent feeding. The new combination soon becomes ineffective, though the original stimulus uncombined is still effective. Conditioned inhibition is an important factor for the acquisition of fearlessness in any occupation which at first excites fear. The instructor makes use of it in training, combining with hazardous manoeuvre a trick or ritual: the man who carries a mascot to support his confidence is using the same method.

Differential inhibition is the name given to a third category of Pavlov's observations. A musical tone, for example, is used to establish a conditioned response. It is then found that a second, neighbouring tone will also excite the response (the phenomenon of irradiation). If subsequently the stimulus of the second tone is several times repeated without feeding, it not only fails to excite but becomes inhibitory. Examples of differential inhibition are easily found under conditions of

For a man who has been exposed to shell-fire the whistle of a near-approaching shell becomes a conditioned stimulus for fear. By irradiation the whistle of any approaching shell, whether near or far, becomes effective to produce fear. With frequent repetition the sound of a shell which will be harmless ceases to excite fear, while that of a shell near enough to be dangerous is still effective. Fearlessness in relation to certain specific stimuli has thus been acquired by differential inhibition.

A fourth variety of inhibition described by Pavlov was external inhibition. This could be induced by an extraneous stimulus eliciting an unconditioned response other than salivation if this were timed to precede the conditioned stimulus. For example, an extraneous sound evoking what Pavlov called the orienting or "Where is it?" response will thus inhibit a well-established conditioned response. The analogy between external inhibition and the inhibition of one affect by another is surely a close one. Psychologists have objected that Pavlov's observations might have been recorded equally well—they would say more accurately—in psychological terms. Pavlov (1941) replied that in such an interpretation the psychologist has adopted the conventional habit of thinking of the

complicated activity of animals in terms of his own feelings and thoughts. The merit of Pavlov's observations is their objectivity.

One general observation made by Pavlov (1941) relevant to the present discussion was a relationship between the type of conditioned response most easily established and temperament. In one group of dogs positive conditioned responses were relatively easily established and well preserved, whereas inhibitory responses were less easily established and more readily lost. These animals he called specialists in excitation. In another group positive responses were established with greater difficulty and were less stable; inhibitory responses were established with relative ease and were more stable. This group he called specialists in inhibition. He observed that his specialists in inhibition were invariably of a timid cowardly disposition, and concluded that there was some inherent relationship between timidity and the preponderance of inhibitory function. As an example he gives the story of a dog born in the laboratory and always gently handled but always timid and shrinking. After some difficulty positive conditioned responses were established. Any extraneous stimulus, however, would abolish the positive responses, leaving the negative (inhibitory) responses. After the Leningrad flood, in which all the animals experienced the threat of drowning, this animal lost all positive responses. They were gradually restored when the original experimenter sat with the animal with the food in the experimental room. Then a trickle of water was allowed to flow under the door; again all positive responses were lost, and had to be restored by the same means as before. This dog is described as a specialist in inhibition. Surely this interpretation is wrong. The animal was, in fact, a specialist in excitation for stimuli of a fear-evoking quality, and the excitation of fear inhibited other forms of response. This interpretation may be applied generally to the distinction between the excitatory and inhibitory types as observed under the restricted conditions of Pavlov's experiments. His specialist in excitation was a specialist of this type so far as the response to food is concerned. His specialist in inhibition was primarily a specialist in excitation so far as the fear response was concerned, and the excitation of the fear response caused inhibition of other responses.

Courage and Confidence

In the acquisition of fearlessness it is evident that courage—persistence with the task despite fear—must play an important part. Persistence despite fear implies emotional conflict. During the exercise of courage awareness of the nature of the conflict and of the emotions involved on either side may be more or less clouded by self-deception. The presence of emotional conflict is, however, manifest by a feeling of tension from which courage is inseparable. In this respect it is essentially different from fearlessness. Courage is generally regarded as the quality most highly to be prized in the soldier, and rightly so, for his duty is bound to lead him where persistence despite fear is indispensable for success; but the soldier's courage is of even greater value in enabling him to acquire fearlessness. This is what we mean when we say that the brave man learns to conquer his fears. It is the fearlessness born of courage which is the greater prize than courage itself—the state of calm rather than the state of tension. What the soldier fears is the anguish of being afraid and having to exert a degree of courage which will absorb his attention and detract from his efficiency. A man of good morale therefore will endeavour by every means to acquire fearlessness, using his courage to this end.

From this discussion of fearlessness and courage I shall now return to the consideration of confidence and loss of confidence in flying personnel. Confidence may be regarded as being compounded of different kinds of fearlessness. Many of these are of the acquired variety (for flying is *ab initio* dangerous) and their acquisition therefore calls for courage. As also experiences of an exceptionally frightening nature are common in flying, and inseparable from operational flying, these various kinds of fearlessness, which are, so to speak, the stones of which confidence is built, are often exposed to stress and not infrequently dislodged: hence loss of confidence, more or less severe according to the number of stones dislodged and their key value in the structure. Courage is again necessary for

repair. The amount of courage which a man needs to acquire and maintain confidence depends upon many factors. The most important of these are included in his pre-flying disposition and his flying experience. Let us try for a moment to imagine some of the fluctuations of confidence in an average pilot from the beginning of training to the completion of an operational tour in heavy bombers. We must suppose that he is by constitution neither exceptionally timid nor fearless. The first time he is air-borne he probably experiences slight fear. Awareness of the fact that flying is an offence against the law of gravity is, I have been told by very experienced airmen, seldom absent from the fringe of attention. Fear, however, is readily inhibited in the average person by the excitation of other affects, such as those involved in professional keenness and by the conditioning of experience. The first solo flight and the first performance of aerobatics again excite fear, which is again readily inhibited by the factors mentioned. In the course of training there are pretty certain to be other experiences of a fear-exciting kind—experiencing or witnessing crashes, death of friends, getting lost, narrow escapes of one kind and another. Most of these do excite fear, though sometimes it may be inhibited. Every time fear is excited the inhibitory state responsible for some kind of fearlessness is weakened. The exercise of courage is then called for. Experience then reconditions inhibition, and from further experience differential inhibition is developed. Meanwhile, however, there is a progressive loss of the fearlessness of inexperience: for the more flying a man has done the greater the number of things he knows which may go wrong, so that with experience the number of situations that are potentially fear-exciting increases, with a correspondingly greater demand upon inhibition for the preservation of confidence. The balance at rest, so to speak, between central excitatory and central inhibitory states becomes more and more in favour of the former. For this reason, even under the relatively harmless conditions of civil aviation, when a man has flown long enough confidence tends to wane. This has been emphasized by Armstrong, and the neurosis which results from the effort to continue flying despite loss of confidence is, I think, what Armstrong (1939) has called *aeroneurosis*. Our hypothetical pilot, however, will not have flown long enough for this. When he reaches the operational training unit there are new dangers to be met arising from the length of trips and bad weather, and at the same time greater stress from fatigue. Now he embarks on his operational career to meet a whole series of fresh hazards. It is certain that these will test his courage, and possible that before the end of the tour the exercise of courage must be continuous, with inevitable tension and strain. So long, however, as he can make use of courage to conquer fears, and by this and other means can preserve his confidence, tension and strain will be diminished, efficiency will be augmented, and he will have courage in reserve to balance exceptional stress. What are the new factors which assail and support confidence in this phase of the airman's career? On the one hand are all the hazards of flying over enemy territory to a target which he knows will be defended by flak, searchlights, and night fighters, new dangers of weather involved in the length of trips, and the risk of bad visibility on return. There is also the effect of casualties. At first he is protected to some extent by the fearlessness of inexperience and by the inhibitory effect of curiosity upon fear. After the first few sorties this protection is lost. This is a critical point in the tour for confidence. As the tour goes on the more stable fearlessness of experience grows, but further experience adds to the number of conditioned fears which need to be inhibited if confidence is to be maintained. The strain of anticipation consequently increases, and the prolonged wait for a sortie cancelled at the last minute is almost as much of a strain as an actual trip. Fatigue, physical and occupational, is an additional factor weakening inhibition, and lack of sleep during periods of intense operational activity operates in the same direction. On the other side there are new factors which help to inhibit fear. High among these ranks squadron and crew morale.

Our pilot, then, having lost the fearlessness of inexperience, finds other sources of fearlessness to support his confidence, but towards the end of the tour a number of factors conspire to weaken the inhibition of fear. There is the increase in the

number of conditioned fears resulting from the unpleasant experiences which he must by now have had; there is the anticipation of relief from strain, and of holiday, which sometimes of a sudden makes life precious and fear insistent; and there is the effect of cumulative fatigue. For all these reasons the structure of confidence tends to become weakened and the call for courage greater. I do not imply that at any time during the tour there has been no demand upon courage. On the contrary, distinguished men of great operational experience have told me that fear, especially before a trip, generally calls for conscious control; but once the sortie has begun there is no fear in excess, and relatively little tension. There is, however, enough tension always, in most men, to cause that fatigue which we are all aware follows a prolonged effort to control emotion. There is reason, from clinical experience, to suppose that the effects of this kind of fatigue are cumulative. For example, a fighter pilot who had won the D.S.O. and D.F.C. and bar was observed by an experienced medical officer to be becoming tense and irritable by contrast with his normally good-tempered disposition. In this instance the suggestion that he needed a rest was disregarded; but later he reported sick, confiding that for several months he had been aware of a conscious effort to control fear while on operational flights. The need for this effort gradually increased, and it was a greater strain to preserve his composure. He had good insight into his condition, arguing that real courage was the ability to overcome natural fear in the presence of danger, but had reached a point when he felt suddenly exhausted.

Lack of Confidence

I have already referred briefly to the effect of a crash with injury in weakening fearlessness and undermining confidence. Several factors operate here besides the crash: there is the fact of being hurt; the opportunity for fear to increase with reflection; and the absence from flying, which by itself can impair confidence. The man who is able to fly again soon after a crash is better placed. Here is the self-revealed story of a fighter pilot who crashed and suffered a head injury and a fractured vertebra, with satisfactory recovery from both. He was sent back to duty apparently keen to fly, but after a short period returned to hospital with vague complaints of pain in his back. He was reassured, and returned to duty. A suspicion was entertained at the time that he had lost confidence, but was dismissed on his own denial; and there the story would have ended had he not unexpectedly written this letter to his physician nearly two years later.

"I can now fly and aerobat an aircraft in a way that fully satisfies me. In fact, I shall now make a confession to you. All the time I was in hospital I was scared stiff of flying. I definitely wanted to fly, but being in the air again just froze me with fright. I kept all this entirely to myself because I thought it would be put down to cowardice. Very stupid of me! When the board eventually put me back on flying, I told them I wanted to fly, when they asked me, for the same reason. I eventually did about nine hours' flying, and most of it was a complete nightmare to me. I was simply scared stiff. But again I kept it all to myself. Then just when I was beginning to overcome my fears, and at the very time when I ought to have been made to fly, I was sent back to hospital. At that time I wondered whether I could continue on with flying when I left hospital, because it meant starting all over again. After that I did about 300 to 400 hours' flying before I really felt an inclination to confidence on just ordinary level flying. Now after 700 hours I have at last got full confidence back for aerobating. When I look back now and think of the agonies I went through it all seems rather amusing. However, the point now is that I am and feel perfectly fit and confident. My back is well, and that is that."

I will now present an example of another kind—that of a sergeant air-gunner, a man of timid disposition in whom fear of flying was never inhibited. He eventually reported sick with dyspepsia, and was told by his medical officer that his symptoms were those of a neurosis, and of a kind which might be due to fear. Next day he wrote to his medical officer as follows:

"Sir,—As you know, I have during the last three or four months been suffering from, as I thought, some minor gastric disorder. This morning I was informed by you that my health is O.K.; and the probable cause of my disorder was mental, or in other words some unconscious fear. After thinking very deeply on the subject for some hours, Sir, I have come to the conclusion that you are right, but only partly so, as you hadn't the whole of the evidence.

"You no doubt have the impression that this fear has only developed over the past month or so. That is not the case. It

goes right back to the very first time I placed my foot in an aircraft. From the moment that craft left the ground I was in the grip of fear and subject to extreme nervous tension. This was not the usual feeling of uncertainty which I suppose everyone experiences on taking this step for the first time. It was real and concrete. Every moment, every bump or bank filled me, and still does, with breathless suspense, and the overwhelming desire to land and get away from it at all costs. My mental impressions to-day have not changed from those of my first flight. I still experience the same cold shivers and fears as I did then, only now more accentuated. If, Sir, these gastric pains are from the aforementioned trouble, I beg to point out that I have tried now for approximately twelve months to overcome the nauseating fear to which I am subject when flying, but, as events have borne out, so far unsuccessfully.

"The only conclusion to which I can arrive is that the trouble is not caused by temporary loss of nerve but by the gradual whittling down of the barrier I have consistently tried to erect between my temperamental equipment and the job to which I am assigned. No one has been more anxious than myself to overcome this complex, because not only has it been a severe blow to my personal pride, but also I have the same abhorrence as I suppose all persons have to being alluded to as 'yellow' or some such designation by my acquaintances."

Although the relation of these stories has occupied some time, I could not without the aid of introspective accounts have illustrated the factors which influence the development of fear and fearlessness in flying personnel. It is to be observed that in none of these cases was there any lack of courage. One of the problems with which the Air Force doctor must be confronted from time to time is the distinction between lack of confidence and lack of courage. That there is such a distinction to be made I hope I have shown. How far a man must be expected to persist in the endeavour to conquer fear is a matter to be decided not by the doctor but by those who face the dangers of operational flying themselves. The principle is that which obtains for all combatant troops. There is, however, a special aspect of the problem for flying personnel, for the state of tension inseparable from the exercise of courage becomes sooner for them a drag upon efficiency. There may come a point for some when, whether they are to be judged medically sick or sound, they are no longer efficient. Whether they are to be disposed of then as brave men or as lacking in moral fibre must be left to the judgment of their peers. The severity of this judgment is a reflection of morale. Severity does not imply lack of sympathy. The distinguished leaders who have spoken to me of their own experiences have often dwelt upon the pain of fear in excess. They have also dwelt upon the happiness and satisfaction of fearlessness, with insight into the means by which in their own case it has been obtained. A fighter pilot who had previously flown light bombers in the Battle of France said that during this time he hardly ever saw targets or the effect of his bombs. After a while he was so frightened that he sweated every time he got into an aeroplane, and could not sleep. Later, in Hurricanes in the Battle of Britain, he found—these are his own words: "Success in the game is the great motive to subdue fear. Once you've shot down two or three effect is terrific, and you'll go on till you're killed. It's of the sport rather than sense of duty that makes you on without minding how much you are shot up." This young officer was severely wounded in combat, but after his recovery went on to destroy many enemy aircraft, win several decorations, and command his squadron.

Here is a case in which the fighter job discovered an affective response which easily inhibited fear. It is an example of that chance matching of stimulus pattern with innate tendency upon which the foundations of confidence are sometimes built.

Conclusion

In this brief view of the human response to flying stress I have dwelt much on the psychological factors, because in the last war they were somewhat obscured by uncertainty about the effects of anoxia and are now more easily discerned. The analysis has led to a somewhat detailed discussion of fear and fearlessness, and to the conclusion that the emotional tension resulting from the prolonged exercise of courage is the most important element of stress. This does not exclude the presence of other important factors which deserve consideration. Skill fatigue in the pilot is one, and has been notably studied by Bartlett (1943), who has shown that loss of emotional control

and abnormal behaviour may be prominent among its symptoms. Fatigue of vision and of hearing, the effects of acceleration and decompression, and even to-day under certain conditions anoxia, also play their part, and all may contribute to central nervous disorder. There are, therefore, effects of flying stress which the clinician will only see truly when he is guided by the psychologist and the physiologist, who in their turn may profit from clinical observation. In the study of the human response to flying stress collaboration of this kind is essential.

My acknowledgments are due to Air Marshal Sir Harold Whittingham for permission to use for these lectures material collected under his direction; to all my colleagues of the Royal Air Force Medical Service who have contributed to and encouraged the work, especially Air Commodore H. L. Burton for his guidance, and Squadron Leader Denis Williams, R.A.F.V.R., for his constant collaboration; to Prof. F. C. Bartlett, F.R.S., for advice and criticism; and, not least, to the General Duty Officers of the Royal Air Force for their invaluable co-operation.

ADVANTAGES OF A DISODIUM-CITRATE-GLUCOSE MIXTURE AS A BLOOD PRESERVATIVE*

BY

J. F. LOUIT, B.M., M.R.C.P.

AND

P. L. MOLLISON, M.B., M.R.C.P.

In another communication (Loutit, Mollison, and Young, 1943) the advantages, resulting from the use of certain citric-acid-sodium-citrate-glucose mixtures as preservatives for stored blood are reported. In assessing the preservative value of these and other recommended solutions the chief criterion adopted was the survival *in vivo* of transfused red cells which were stored in the various solutions. By this test the citric-acid-sodium-citrate-glucose mixtures were found to be definitely superior to the standard M.R.C. (1940) trisodium-citrate-glucose mixture and slightly better than the Rous-Turner (1916) solution. Moreover, these acid solutions had the additional advantage that they could be autoclaved entire with but little or no caramelization, whereas to avoid this with the M.R.C. and Rous-Turner solutions the glucose and the alkaline trisodium citrate have to be autoclaved separately and later mixed aseptically.

Of the acid solutions tested, however, all had minor disadvantages. Only one solution developed no caramel at all on autoclaving, and this solution was rather deficient in citrate ion, so that clotting of the blood was not infrequently observed. With the other solutions, which contained more citrate, a certain amount of caramelization occurred on autoclaving. This could be prevented by increasing the amount of citric acid in the

* A Report to the Medical Research Council from the South-West London Blood Supply Depot.

mixture, but then increased haemolysis of the blood occurred during storage. It has therefore been necessary to continue the trial of acidified citrate-glucose mixtures to find one that satisfies more completely the following criteria: (1) improved preservation, as judged by survival tests *in vivo*, on comparison with the present standard M.R.C. solution; (2) absence of caramelization on autoclaving; (3) a content of citrate ion adequate to prevent clotting even when the blood is not perfectly mixed with the solution during taking.

From among many possible suitable formulae the one selected for trial was:

100 c.cm. of 2% disodium citrate (monohydric)
20 c.cm. of 15% glucose (or 10 c.cm. of 30% glucose)

for admixture with 420 to 430 c.cm. of blood. This mixture, autoclaved in the standard M.R.C. bottles, with caps loose, at 20-lb. pressure for 30 minutes in the standard vertical, gas-heated, air-jacketed autoclaves supplied to the War Emergency Blood Transfusion Services, gives a colourless solution. Disodium citrate, moreover, has one other practical advantage over citric-acid-trisodium-citrate mixtures in that a single substance only has to be weighed.

Methods

Blood from healthy donors of Group O was taken into the above solution and stored at 2° to 6° C. for 20, 28, or 45 days. On the day of the test transfusion a concentrated cell suspension was prepared by removing the bulk of supernatant plasma from two bottles of identical age and pooling the packed red cells. Patients of Groups A and B whose anaemia was thought not to be due to haemorrhage or haemolysis were chosen as recipients. The transfusion was usually completed in 60 minutes. Venous samples were taken before transfusion, 5 minutes after transfusion, and thereafter at convenient intervals (usually 24 hours, 7 days, 21 days, and 60 days). The number of surviving donor cells was estimated after carrying out differential agglutination by Dacie and Mollison's modification (1943) of Ashby's technique. In every case a pre-transfusion sample was tested, and the small number of unagglutinated cells found was subtracted from all subsequent counts of unagglutinated cells.

In order to determine the efficacy of the solution as an anticoagulant an examination was made of the number of clots found among the red-cell sediments of bottles that were being used for plasma production. The red-cell sediments were passed through four layers of gauze, and any clots found were weighed wet. A similar test was made of blood stored in two other solutions—namely, Murray's solution (1943), and a mixture of 90 c.cm. of 3% trisodium citrate, 10 c.cm. of 3% citric acid, 10 c.cm. of 30% glucose with 430 c.cm. of blood (solution No. 2, investigated by Loutit, Mollison, and Young).

Results

Two patients received blood stored for 20 days, 7 patients received blood stored for 28 days, and 2 patients received

* From Mollison and Young (1942).

† From Loutit, Mollison, and Young (1943).

"M.R.C." stands for the present standard trisodium-citrate-glucose mixture.

"Disodium-citrate-glucose" is the solution under trial.

45-day-old blood. To make a direct comparison, transfusions of blood stored for 28 days in the present standard M.R.C. trisodium-citrate-glucose solution were also given to 5 patients,

and survival was estimated. The results are shown in the accompanying Table, and for comparison some of the results obtained in two previous trials are included.

When the figures for blood stored for 28 days in this disodium-citrate-glucose and the M.R.C. mixtures are compared, the striking superiority of the former solution is clearly shown. For instance, 7 days after transfusion 74% of erythrocytes stored in the disodium citrate mixture are surviving, compared with only 22% of the erythrocytes stored in the present trisodium citrate solution.

Clot Formation.—Sediments (1) from 196 bloods stored in the disodium mixture, (2) from 132 stored in Murray's mixture, and (3) from 198 stored in "solution No. 2" were filtered. The numbers and weights of the clots were as follows: (1) 196 bloods, 27 clots, total weight 355 g.; (2) 132 bloods, 34 clots, total weight 894 g.; (3) 198 bloods, 5 clots, total weight 22½ g.

Discussion

As will be seen from the Table, the survival of blood stored in the solution under trial is far superior to that of blood stored for an equivalent period in the present standard M.R.C. solution. From the point of view of survival, blood stored for 45 days in the disodium-citrate-glucose solution compares favourably with blood stored for only 28 days in the present standard citrate-glucose mixture, and blood stored for 20 and even for 28 days in the disodium citrate solution is not greatly inferior to fresh blood as a source of viable erythrocytes.

The only disadvantage of the disodium citrate solution is its liability to permit clot formation if the blood is not carefully mixed with the solution during taking. Maizels (1943) has calculated that 10 mM. of citrate in the final citrate-glucose-plasma mixture is adequate to prevent clotting with moderately energetic rotation of the tilted bottle. 420 c.cm. of blood diluted with 120 c.cm. of Murray's solution contains only approximately 10 mM. citrate, and it is therefore not surprising that clotting sometimes occurs; the present disodium citrate mixture, however, contains double this quantity, and careless taking is thus probably responsible for the large number of clots found in the present test. With care it should be possible to avoid clot formation completely. Using a modified technique in the collection of blood, the following results have been obtained: 75 bloods stored in the disodium-citrate-glucose mixture gave 5 clots, total weight 75 g.

Summary

A mixture of 100 c.cm. of 2% disodium citrate with 20 c.cm. of 15% glucose (to be added to 420 to 430 c.cm. of blood) has two advantages over the present standard trisodium-citrate-glucose mixture as an anticoagulant and preservative solution for blood storage: (1) Its preservative power, judged by the survival *in vivo* of erythrocytes stored in the solution, is considerably superior; (2) the mixture can be autoclaved entire without the production of any caramel.

The mixture, however, contains less citrate radical than the standard trisodium citrate solution, and greater care must be taken to secure thorough mixing of blood and solution if clot formation is to be avoided.

L. Chargin, N. Sobel, and H. Goldstein (*Arch. Derm. Syph.*, 1943, 47, 467) record an epidemic of erythema infectiosum in a New York City orphanage from Nov. 4, 1941, to April 11, 1942. There were 80 primary attacks, and 90 relapses numbering from one to six. The severest attacks were among girls. In 64.7% the eruption was limited to the face, in 2.3% it was confined to the body, and in 33% both the face and the body were affected. Infants and children between 1 and 4 years were relatively immune. The incubation period was from one to twelve days.

PROGRESSIVE CEREBRAL ISCHAEMIA

BY

TREVOR H. HOWELL, M.R.C.P.Ed.

Captain, R.A.M.C.; Deputy Physician and Surgeon, Royal Hospital, Chelsea

Elderly people who are beginning to "fail" often show changes in mentality or behaviour as the first sign of their deterioration. During the last two years a number of such patients have been studied at the Royal Hospital, Chelsea. Among them were two groups of cases which seemed to be associated with the presence of cerebral ischaemia. One of these, in which the condition remained stationary, appeared to correspond to the "relative hypotension" of Stieglitz (1935). This was one of the commoner forms of senile dementia. The other, described below, was progressive through three distinct stages to a fatal termination.

Clinical Picture

Of the 27 patients in this series all but two were Chelsea pensioners. Their ages ranged from 70 to 87. Fifteen had but recently recovered from an infection of the respiratory tract; 14 were suffering from congestive heart failure, which followed bronchitis or bronchopneumonia in 7 of them; 9 had had previous cerebral thrombosis; 1 had infection, cerebral thrombosis, and heart failure; while 1 had no known predisposing factor apart from hypertension.

TABLE I.—Predisposing Factors

Recent infection	15
Congestive heart failure	14
Previous cerebral thrombosis	9
Infection and heart failure	7
Heart failure and cerebral thrombosis	4
Infection and cerebral thrombosis	4

The first change to be noticed was a vague or muddled state of mind in a patient previously lucid. Thought processes became irregular and sometimes delusions appeared. These might be of persecution by members of the staff or others, but often concerned the price of articles. For instance, one man asked for £150 to buy a pipe and tobacco; another patient watered an imaginary garden with his urinal; while a third sprinkled his pudding with tobacco. Failure to recognize friends or relatives was also common. Members of the hospital staff might be addressed as brothers or sisters in error. At this stage the blood pressure was high in most of the cases recorded, but not so high as the previous normal. A fall from 230 to 170 mm. or from 205 to 195 mm. was the type of change noted.

After this came a stage of restlessness, often going on to violence, and usually worse at night. The most characteristic feature was a desire to get in and out of bed without reason. Automatic resistance to nursing or treatment was common.

In some cases the clinical picture resembled the condition known as "cerebral irritation," seen after head injuries. Two patients in this stage had to be sent to a mental hospital, but died in cardiac failure soon afterwards. The blood pressure in this phase was definitely lower than before, varying from 110/100 to 110/70 in patients previously hypertensive.

As the restlessness passed off the pulse became perceptibly weaker and the patient drifted into a terminal coma at systolic pressures between 120 and 75 mm. Diastolic pressures were always hard to determine at this stage, but one man showed 95/80 mm. as his last reading. His original figures were 180/90 mm. Another patient lingered for three days with no pulse palpable below the elbow, although his previous level

TABLE II.—Symptoms and Blood Pressure (in mm.) of Typical Cases

Case	Usual B.P.	Muddled or Delusional	Restless or Violent	Comatose	Duration
5	?	120/90	110/80	95?	28 days
6	?	190/90	110/70	?	5 days
9	?	140/90	110/80	75?	1 month
11	205/140	195/100	130/80	105/60	13 days
15	230/110	170/110	?	brachial 0	21 months
18	?	150/120	150/100	120/80	5 weeks
21	180/90	160/90	130/80	95/80	2 months
24	180/90	150/80	130/70	110/60	21 days
25	225/130	150/100	130/100	110?	1 month
26	?	150/110	150/90	100/60	9 weeks
27	?	170/90	140/80	110?	5 weeks

had been 230/110. At this stage it was usual to find peripheral cyanosis and evidence of circulatory stagnation.

Discussion

The first cases in this series came to notice because the condition relapsed after apparently successful treatment. For example, patients with bronchopneumonia cured by sulphapyridine returned in congestive heart failure. This was treated by administration of digitalis and injections of mersalyl, which removed the oedema; but the patients showed the successive mental symptoms described, and died in spite of all effort. It was then observed that many of them had been previously hypertensive or showed cardiac enlargement suggesting high blood pressure; so readings were taken at intervals. Unfortunately enemy action destroyed many of the early records.

The relation between a falling blood pressure and the appearance of cerebral symptoms in arteriosclerotic subjects suggests that progressive cerebral ischaemia is the basic pathology. This was mentioned by me in a communication (Howell, 1941) on the subject of heart failure in the aged. Subsequent cases, with more detailed study of the arterial tension, have gone to confirm this. Successive ischaemia of cerebral cortex, hypothalamic area, and medulla would likely to give the symptoms described. Owing to the favourable outcome of this syndrome its recognition is of some prognostic importance to the practitioner.

Conclusions

A series of cerebral symptoms occurring in 27 senile patients is described. A progressive fall in blood pressure accompanied the symptoms in every case which had such readings taken. It is suggested that the symptoms were caused by progressive cerebral ischaemia. The invariably fatal prognosis of this syndrome is stressed.

CONGENITAL ABSENCE OF THE VAGINA
TREATED SUCCESSFULLY BY THE
BALDWIN TECHNIQUE

BY

THOMAS O'NEILL, F.R.C.S.

Surgical Chief Assistant, Manchester Royal Infirmary;
Late Assistant Surgeon, E.M.S.

Operations for the treatment of congenital absence of the vagina have been performed since the end of the last century. The basis of these operations was dissection of the recto-vesical space, and lining by epithelium or endothelium of the cavity thus produced. Heppner (1892) used skin from the thigh; Pozzi (1908), flaps from the labia; while Thiersch (1909) used flaps from the rectum. Others have employed grafts, pinch grafts, or peritoneum have been employed. Wharton (1940) merely dissects the recto-vesical space and inserts a rubber-covered mould, which is worn for about four months. He claims that by the end of that time epithelium has grown up from the orificium to line the cavity. He states that contracture has not occurred in any of 11 cases done by his method. This is difficult to understand, as contracture is the bane of all operations where bowel is not employed.

Snegireff (1904) used the rectum to replace the missing organ and a modification of his operation was designed by Schulz (1911, 1912). In the modern construction of the vagina from bowel a loop of pelvic colon or ileum is employed. Baldwin (1907) was the first to describe the technique of using small intestine. His operation was performed in the case described below.

Clinical History

The patient was aged 25, had been married two years, complained of primary amenorrhoea. Her secondary characteristics were well developed and her libido was normal. She was mentally depressed owing to her deformity. Exam-

tion showed a normal pudendum, except that the vagina could not be found. On rectal examination the ovaries could be felt, but the uterus was not palpated. Intravenous pyelography showed that the kidneys were normal in position and function. The patient was extremely anxious for operation and willing to accept its limitations.

Report of Operation

The operation was performed in July, 1942. The patient was placed in the lithotomy position and the recto-vesical space dissected up to the peritoneum. A long tissue forceps was put in the cavity and the Trendelenburg position adopted for the second stage of the operation. The abdomen was next opened by a right paramedian incision: the ovaries, tubes, and round and broad ligaments were present, and looked normal. The appearance was as if a total hysterectomy had been performed. The lowest loop of the ileum was "measured" over the pubis. This loop was excluded from the intestinal tract by dividing the bowel between clamps, about six inches from the ileo-caecal valve, and again about ten inches higher up. The ends of the separated loop were closed and its mesentery was mobilized for about two inches, care being taken that its blood supply was not jeopardized. Bowel continuity was restored by end-to-end anastomosis. Aided by an assistant pushing on the forceps, the peritoneum in the pouch of Douglas was divided. The forceps was made to seize a ligature passed through the centre of the mesentery of the loop, and the assistant pulled forceps and loop down. This was the most difficult part of the operation, and could only be done when the Trendelenburg position had been abandoned. The peritoneum was sutured over the ends of the loop and the abdomen sewn up in layers. The lithotomy position having been again adopted, the convexity of the loop was sutured to the orificium and opened. A corrugated drain was left in the recto-vesical space for 24 hours.

The patient stood the operation well; the spur was crushed after three weeks and again a week later. She left hospital six weeks from the time of operation. The vagina was now four and a half inches long and admitted two fingers. Her stay in hospital was prolonged because of superficial infection of the abdominal wound. She was seen again in six months: her cheerful attitude towards life was a striking change. The vagina had not contracted, and she had no noticeable mucous discharge.

Conclusion

One case of congenital absence of the vagina treated successfully by the Baldwin technique is described. When uterus and ovaries are normal there can be no question as to the propriety of operation. In the type of case described above it is felt that operation is justifiable if the patient is married or about to marry, if her attitude towards sex is normal, and if she is willing to undergo an operation of some severity.

From absence of personal experience, no comparison is made with other methods of treatment. It may be said, however, that the vagina constructed by this method shows no disposition to contract, is lined by mucous membrane, and on bimanual examination is almost indistinguishable from the normal vagina.

W. I. Daggett (*J. Laryngol. Otol.*, 1942, 57, 427) describes a condition of desquamative otitis externa which is rarely if ever seen in Great Britain, but is well known in hot humid climates such as Malta, where he has seen 164 cases. The incidence is seasonal, the disease being very common in the summer and virtually disappearing in the winter. The chief characteristic is desquamation lining the deep bony meatus. The commonest bacteriological findings are diphtheroids plus *B. proteus*, and diphtheroids plus *B. pyocyaneus*. Treatment consists in careful cleaning, astringent wicks, and powder insufflation.

Medical Memoranda

Two Cases of Congenital Absence of One Kidney in the Same Family

Although congenital absence of a kidney is not rare enough to warrant the reporting of a case—A. R. Stevens (1937) estimated its occurrence as about 1 in 1,000—two cases in the same family are of interest in suggesting that the condition may be hereditary. More than one case in a family does not appear to have been recorded before: Ballowitz (1895) gives a summary of 210 cases, and reports 3 new ones, but no mention is made of the condition being familial or hereditary.

CASE REPORT

The patient, a boy aged 8, was sent for investigation because albumin had been found in the urine at a routine pre-operative examination. He was in good health, and had no symptoms referable to renal disease. He had had a tonsillectomy at the age of 6. The mother's uncle was known to have had "kidney trouble."

On examination the boy appeared well. Neither kidney was palpable. The heart was normal, and the blood pressure 110/70. The urine showed no albumin at any time, even after the boy had been up and about. Microscopy of the urine revealed a very occasional pus cell and red blood cell, but no casts. The blood urea was 42 mg. per 100 c.cm. The urea clearance was 103% of the average normal. An intravenous pyelogram showed a large but normal left kidney in a normal position, but the right kidney outline was not visible and there was no visible secretion from it. Cystoscopy revealed a normal left ureteric orifice, but no right ureteric orifice was visible. The interureteric bar was seen up to the midline, but no sign of it was present on the right side. No other congenital deformity was found.

Further inquiry about the condition of the mother's uncle was then made, and it was found that two intravenous pyelograms had failed to reveal any kidney on the right side, the left kidney being large, with normal outline of the calices, pelvis, and ureter. The absence of the right kidney was confirmed by palpation during an appendicectomy.

The occurrence of the identical abnormality in two members of the same family suggests that the condition may be hereditary, and is a stimulus to search for more such cases.

I have to thank Dr. W. J. Pearson for permission to publish this case, and Mr. F. J. F. Barrington for doing the cystoscopy.

J. P. BOUND, M.B., B.S.,

House-physician to the Children's Department,
University College Hospital.

Sealing Intratracheal Catheters, and a Listening-tube

I have tried various ways of sealing intratracheal catheters in position to prevent loss of cyclopropane through leaks and to gain control of intrathoracic pressure, and for some years have relied, except for operations in the mouth and some others entirely on the following:

1. The soft parts about the glottis—the base of the tongue, epiglottis, aryepiglottic folds, etc.—are themselves pressed into service to occlude the space where leaks occur. This is done by approximating them to the posterior wall of the pharynx by tying the chin back with two turns of bandage, and is facilitated by the phenomenal relaxation of the jaw under cyclopropane. The method has the advantage of being very simple and efficacious, and it is harmless. The use of packing is avoided, and the only care needed is to keep the tongue, which is protruded from the half-open mouth, moist. Moreover, an ordinary Magill catheter is used, whereas an inflatable cuff, when wrinkled, may impede blind intubation. In some patients the face becomes congested.

2. It is a great help to be able to hear the breathing well, and in cases which have been intubated but not connected to a breathing-bag I cut a piece of rubber tubing, a few inches long by 3/8 in. diameter, to use as a listening-tube in the following way: Near one end a slit 3/8 in. long is made, and diametrically opposite to this a piece is cut out of the wall with scissors, leaving a large hole; the other end is cemented with rubber solution on to a length of tubing of smaller diameter for conveniently holding to the anaesthetist's ear. The slit is slipped over the collar of a Magill metal connexion, and so the breath goes in and out past the hole. It can be most clearly heard, and has been much appreciated by students, who are thus enabled to heed every change in the breathing.

K. B. PINSON, M.R.C.S.

Reviews

INDUSTRIAL MEDICINE

The Principles and Practice of Industrial Medicine. By 32 authors. Edited by Fred J. Wampler, M.D., Professor of Preventive and Industrial Medicine, Medical College of Virginia. (Pp. 579); Illustrated. 56.00 or 33s.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1943.

This is an extremely timely textbook, and is admirably written by 32 authors—each an expert on his own branch of work. Industrial medicine is a subject whose importance has been adequately recognized only since the present war began. Comprehensive textbooks are few, and therefore this excellent one should be greatly appreciated both by industrial medical officers and by students. Unfortunately legal and compensation matters are not identical in the United States and Great Britain, and therefore in this country it is not a book of reference on these subjects. However, practice runs to a great extent parallel, and this does not detract greatly from its value for the student. It begins by giving an excellent account of the place of the physician in industry; there is a very sane discussion on relations with management, supervisors, foremen, and workers. This is followed by the position of Governmental agencies in industrial hygiene. The full importance of environment is recognized by chapters on temperature, humidity, atmospheric pressure, lighting, and ventilation. The survey of substances which cause occupational poisoning is first-rate. The relation of gradations in degree of toxicity to the periodic classification is stressed. Kehoe gives the benefit of his experience in a chapter which is an up-to-date review of the present state of our knowledge of lead poisoning. Chapters on solvents and dust diseases complete the section devoted to occupational diseases. It is noticeable, however, that no mention is made of byssinosis, or diseases resulting from the use of compressed-air tools.

The last part of the book is devoted to prevention, trauma, and rehabilitation, all of which are admirably discussed, though it is surprising that only one short paragraph is devoted to a discussion of the place of mass miniature radiography in detecting the early case of pulmonary tuberculosis. Diagrams and illustrations are scattered throughout the book, and each chapter has a comprehensive bibliography. In general this is an excellent pioneer textbook which should be of much value in redressing the balance of medical education. We hope that it will have a great success and will be extensively read. Its sins are those of omission, which are almost inevitable in such a pioneer book, and will doubtless be corrected in future editions.

DISEASES OF THE BREAST

Diseases of the Breast: Diagnosis, Pathology, Treatment. By Charles F. Geschickter, M.D. With a special section on treatment in collaboration with Murray M. Copeland, M.D., F.A.C.S. (Pp. 829; Illustrated. 72s.) London: J. B. Lippincott Company. 1943.

The author of this important volume is a pathologist of high distinction, especially in the field of experimental pathology of tumours and their relation to endocrines. To this experience he has added a study of cases seen in the wards of Dean Lewis at Johns Hopkins Hospital and of the case-histories, specimens, and follow-up studies recorded in the surgical laboratory of Johns Hopkins and therefore largely the work of Halsted, Welch, and Bloodgood. It is from its pathological aspects, and still more from its account of experimental pathology, that the book derives its importance, and it would, perhaps, have made for clearness if the author had separated the laboratory methods, of which he is a master, from the clinical aspects of the subject, which might well have made a special study.

The opening chapters deal with the development and physiology of the breast, especially in relation to endocrines, and here the author has made full use of his wide experience in the mammary evolution of the rat and the monkey. This is followed by an account of mammary hypertrophy, of puerperal changes, and of chronic cystic mastitis, which is discussed at great length and with full reference to experimental work on animals, and this is followed by well-illustrated chapters on non-malignant tumours.

One-half of the volume is rightly devoted to cancer of the breast, and from the pathological and experimental points of view this is certainly the most important part of the book. When, however, actual treatment is taken up there are numerous statements with which we cannot at all agree, and which would seem to us to be entirely out of date; for example no one nowadays thinks it necessary to remove large portions of skin, nor when a surgeon undercuts the skin would regard sloughing as even a distant possibility. The problem of irradiation is discussed at considerable length, but one who have welcomed a fuller critical account of its advantages, disadvantages or of the complications which may arise. The volume concludes with chapters on the experimental production in animals of chronic cystic mastitis and of cancer by injection of oestrogen and hormones.

It will be seen that the book is essentially a pathological review for the study of the expert who wishes to make himself familiar with the results of experimental methods, combined with an analysis of a large amount of clinical material by surgeons who were leaders of their time. It is superbly illustrated, and each section is provided with full bibliography.

MENTAL HEALTH OF UNDERGRADUATES

Mental Health in College. By Clements C. Fry, M.D., with the collaboration of Edna G. Rosow. (Pp. 365. 52.00 or 11s. 6d.) New York: The Commonwealth Fund; London: Oxford University Press.

Nearly 20 years ago the authorities at Yale University heart-searchings because while so much was done for intellectual and physical well-being of their students little was done to help their general adjustment to a new life. A college community in the United States is a rather formidable world for some to face, as the life is highly organized and competitive. "With its residential colleges, fraternities, senior societies, its numerous student activities and high scholastic standards, Yale is a community which makes insistent demands upon its members." A department of psychiatry (using that word in its wider American sense) was therefore instituted to help students to make adjustments to it. At a survey of all entrants was attempted, but, as might have been anticipated, the results were incommensurate with the labour involved. Then students in difficulty were referred by their teachers to the department or came of their own accord. Naturally, the best results were achieved among those who came willingly. This book is a statement of the observations made and conclusions reached. Typical problems are considered in turn—difficulties with family relationships, scholastic achievement, social adjustments, and so on. Case histories are embedded in the text. Frankly, we do not think this is the best plan. Seldom does one of these causes exist in isolation; they are generally interwoven. Thus there is a good deal of repetition which is accentuated by the monotonous similarity of the case histories. A more general discussion, with the case histories relegated to an appendix to which reference could be made by way of illustration, would have increased the pleasure of reading the book without detracting from its value as a record. Nevertheless many interesting results emerge.

It is not surprising that the parental relationship bulk largely in these discussions. As Otto Rank said, the development of the growing personality from the parents is one of the most essential stages, as it is the most painful, in development. Between dependence on the security and affection of the home on the one hand and subjugation by parental domination on the other, many a young life is faced by a veritable Scylla and Charybdis. Moreover, domination is not always harsh; even more often it is affectionate, but too intrusive. In the present volume we meet with many instances of old Yale men urging, from loyalty to his alma mater, academic life on a son who is completely unfitted for it. "Broken homes" present another aspect of this problem. Desire for social acceptance seems an extraordinarily powerful influence at Yale; fraternities abound which are governed by strict ritual and surrounded by an atmosphere of secrecy and solemnity. Failure to obtain election to the desired one often seems to have a very depressing effect on the student. This is quite unlike the informal clubs abounding in our universities, which no one, either inside or outside them, takes very seriously. As to problems arising from scholastic duties, it is surprising to learn that in the first year more

20% have to drop out because they fail to reach the intellectual standard required; between a quarter and a half of these cases were due to insufficient earlier education, but in the remainder the pre-college record had been satisfactory. This surely suggests too intensive pressure is exerted on them.

A comparison of the reactions in the various faculties gave interesting results. The divinity students are of a higher average age but of poorer financial status. It is the fundamentalists finding themselves in a more liberal atmosphere who chiefly provide the problem cases. The medical students are given more opportunities of developing their own initiative, and the authors are surprised, though we are not, that this appeared to diminish difficulty of adjustment. Such difficulties were chiefly among those who found they had chosen the wrong vocation. Curiously enough the medical students were the group to show the most resistance to psychiatry. The law students, again an older group, showed the greatest uniformity of symptoms, which were generally those of an anxiety state centred on the gastro-intestinal tract.

Now that Yale has adopted the residential system it becomes of interest to compare experiences there with those of the older universities in this country. On the whole their students enter younger, and in the majority of cases ours have already become more detached from home influences at boarding-schools. Nor have we to deal with considerable numbers of the sons of foreign immigrants, to whom a Yale degree represents prestige and yet more difficulty in social adjustment. It would also seem that the atmosphere is more fiercely competitive than here. It may be that we are apt to be too complacent in our view that adolescence is a condition which soon cures itself, and are rather reticent about probing the personality of others. Nevertheless there are grounds for believing that psychoneuroses are less common in undergraduates in England than in the States. Probably the recent generations are more subject to them than their fathers, who were brought up with a stable background which imparted a sense of security. State scholars are sometimes a problem, when a well-meaning local authority insists on sending up students who are unsuitable. These do not like the university life and yet become dissatisfied with home conditions; they swell the third class and find it difficult to fit into life afterwards. Both at Yale and here the conclusion seems to be that a university career is not for all. As a parodist of the Grand Inquisitor's song in "The Gondoliers" wrote:

"For no one is of high degree
When everybody's got one."

Notes on Books

Vol. II of the new series of *Clinics* published by Lippincotts contains a symposium on haemorrhagic states, blood substitutes, and the management of haemolytic states, as well as a review of haemoglobinuria. In addition there are articles on such widely different topics as meningitis, fibrositis, burns, and abortion. The reviews are competently written, but it is a little difficult to know to whom they are addressed. The haematological subjects have already been reviewed *ad nauseam* and there is little significant recent progress to report. The material is perhaps too detailed for the practitioner and not fundamental enough for the researcher. It is also probable that the articles on blood banks and burns would not be regarded as absolutely up to date by those working in these subjects on this side of the Atlantic. This is because much of the most important medical research of the war is still locked in the secret archives of the United Nations. The time has surely come for the authorities to consider the orderly release of some of this material, and when this happens it may well require all our present facilities for reviewing. But until then it is pertinent to ask whether American publishers are not overdoing the business of reviewing medical progress.

A pamphlet describing the steps being taken in schools and youth organizations to give sex education to children and young people has been published by the Board of Education. *Sex Education for Children and Young People* (H.M. Stationery Office, 6d.) is based on a recent survey by H.M. Inspectors and is published for the benefit of local education authorities, teachers, and youth leaders, and of parents who wish to give their children some guidance. One of the main conclusions of the survey is that far too many young people to-day are ill informed on the facts of sex and ill advised regarding their social implications. This is mainly due to the absence of sex instruction in early years by parents and subsequently

in the schools. To assist parents the Board strongly urges education authorities to arrange parents' meetings with a view to securing their co-operation in everything that is done in the schools and helping them in dealing themselves with their own children. It is estimated that about one-third of the secondary schools in England make a serious attempt to give instruction. Though most secondary schools claim to offer some sex instruction, in many cases it is confined to individual advice. Some progress has also been made in the elementary schools, but the present school-leaving age is generally recognized to be a severe limitation in dealing adequately with the social and moral implications of sex conduct. The pamphlet emphasizes two main stages in sex education: (i) factual instruction in the physiology of sex (this usually forms an integral part of a normal course, such as biology or general science); and (ii) guidance to groups or individuals towards a better understanding of the sexual impulse and emotion and the moral and social problems arising from it. In the schools the first element is best dealt with through class teaching; this helps to avoid any special emphasis. It is found that it is advisable for children to receive this practical background before adolescence gives an emotional colour to the subject. Guidance on questions of conduct comes later when the child is more mature. The pamphlet stresses that simple and sensible answers should be given to children's questions from the earliest age.

Despite wartime difficulties *Recent Advances in Medicine* appears in a new edition (the eleventh), and in it Dr. G. E. BEAUMONT and Prof. E. C. DODDS continue their critical review which they began nearly 20 years ago. Nearly one-fourth of the present volume consists of new material, and certain familiar sections of various editions have had to be excluded. Physicians and practitioners will find much of interest between the covers of this book, which is published by J. and A. Churchill at 18s.

Preparations and Appliances

SYRINGE FOR TRANSFUSIONS AND INFUSIONS

Dr. LEONARD ROSENTHAL, senior resident medical officer, Staincliffe County Hospital, Dewsbury, writes:

The syringe here described was devised to facilitate the transfusion of blood and the intravenous infusion of plasma, saline, glucose, etc. It has been used for venesection, and should prove useful in taking blood from donors and in continuous intravenous anaesthesia.

It consists of a 1 c.cm. Record syringe the piston and piston-stem of which are hollow, being formed with a uniform bore throughout their length. Towards the end of the piston-stem is attached a tap manipulated by a small lever, while the end of the piston-stem is adapted for the fitting of rubber tubing.

In use, the syringe is connected to the reservoir of fluid to be infused and the whole apparatus, including an intravenous

$\frac{3}{4}$ Scale
Patent applied for

needle attached to the syringe, is filled, with the tap on the piston-stem open and the piston fully withdrawn. The tap is then closed and the piston driven "home." The syringe with the tap closed is, in effect, like any ordinary syringe, and is now used as in taking a blood sample from a vein. As soon as the vein is entered, shown by blood flowing into the barrel, the tap is opened and the perfusing fluid allowed to run through into the vein. The syringe is then strapped to the arm.

By the use of this syringe dissection of the vein is avoided and the same vein can be used repeatedly. Again, because the syringe is a vein-seeker there is no doubt when the needle is in the vein. This makes it especially useful when the veins are difficult to locate. Starting the transfusion or infusion is simple and can be accomplished by a finger of the same hand that holds the syringe. The glass barrel provides a "window" through which continual inspection of the perfusing fluid can be made. Any blockage of the apparatus, as sometimes occurs in blood transfusion, can be overcome without withdrawing the needle from the vein. All that is necessary is for the piston to be withdrawn to its full length, the tap closed, and the contents of the syringe injected into the vein. The opening of the tap will then restart the transfusion. This syringe has been in use for over a year for routine and emergency work, and its simplicity in both design and operation has saved a great deal of time in transfusion procedures. It may be found useful in the emergency transfusions in the field.

My thanks are due to Mr. James Walker, who made the original syringe from my design. It is now being manufactured by Chas. F. Thackray, Ltd., Park Street, Leeds, 1.

PENICILLIN IN BATTLE WOUNDS

The Tunisian experience of which Prof. H. W. Florey gave a necessarily brief account to a crowded audience at the Royal Society of Medicine on Nov. 9 (*B.M.J.*, Nov. 20, p. 654) is fully described in a War Office Report of which we give a summary on p. 755. It appears that this report is for official circulation only; it is to be hoped that copies will reach all those who are engaged in the clinical use of penicillin, since it is by far the fullest account of this form of treatment so far written, and contains a mass of valuable information both on general principles and on details of surgical technique. The circumstances in which this study came to be made are now fairly well known. The work of Florey and others during the past two years had shown that penicillin is capable of controlling infection by almost any of the pathogenic Gram-positive bacteria which occur in wounds, and the possible applications of this fact to military surgery had clearly to be investigated as a matter of prime urgency. Clinical material in quantity was available only in North Africa, and accordingly Florey himself with Brigadier Cairns went out there for three months, and collaborated with a trained surgical team in forward base hospitals in Tripoli and Sousse in the treatment of early casualties from the campaign in Sicily. A preliminary study in Algiers of the treatment of chronic wound sepsis had been disappointing: local treatment with penicillin was often ineffective, and only prolonged systemic administration involving heavy and perhaps unjustifiable expenditure of penicillin could be relied on to bring infection under control; even this failed in some cases.

The circumstances of the Sicilian campaign were well suited for a trial of reasonably early though not immediate penicillin treatment. In a few cases treatment was in fact more or less immediate: 13 wounds were operated on in hospital ship off the Sicilian shore, being closed after introduction of undiluted penicillin powder—the only instances in which penicillin was used in this form. The great bulk of the cases were 3 to 12 days old on arrival at the forward base in North Africa; the majority were infected and some frankly septic and dirty, although some had been kept clean by the insufflation of penicillin-sulphanilamide powder in the forward area. With or without further insufflation, every possible soft-tissue wound, however large and regardless of sepsis, was completely closed, small tubes being left in through which penicillin solution was injected twice daily for 4 days. In the great majority all Gram-positive infection was eliminated at a small cost in penicillin; either the wound remained dry, or a benign sort of "Gram-negative pus" (containing *Ps. pyocyanea*) could be aspirated or escaped from the wound, its formation not apparently retarding healing. The other main class of case was the compound fracture; here again closure was the policy, in order to

obviate chronic infection. These cases received 500,000 units of penicillin by systemic routes, a dosage which may have to be increased somewhat, especially for fractures of the femur. In these two main classes the numbers of men treated were 171 and 36 respectively. Accounts are also given of the local treatment of 23 brain wounds and 7 cases of gas gangrene.

That this study should have been compressed into a space of only three months, during which successful new methods were devised and tested on a considerable scale, is an achievement with which its authors have every reason to be well satisfied. It is said that the investigation has been criticized on the ground that it was "uncontrolled" in the sense that no parallel series was treated by other methods. A vigorous rejoinder to this comment points out that any such comparison would require a far longer period of study, and goes on to observe that in spite of four years of war there are as yet no data by which the merits of sulphonamide wound treatment can be judged. Somewhat acid comments are made on the existing lack of statistical information generally: there are no large-scale figures available concerning the frequency of wound infections or their duration, still less of the effect on them of any particular form of treatment. The appointment of statistical officers to assemble such data for both penicillin-treated and other cases is recommended. It is difficult to envisage a strictly controlled investigation, since it is repeatedly stated or implied that no surgeon would have considered closure of some of the large and dirty wounds which were treated but for the assurance that penicillin would enable him to get away with it. That there was not one disaster in consequence of this often drastic and difficult proceeding is perhaps the most encouraging single feature of the whole report. The absence of controls is also excused on the ground that penicillin treatment should not be compared with any other until its technique has been perfected. With more experience it is anticipated that methods and results will be improved.

It may well be considered that Florey and Cairns have already succeeded in their object of discovering how penicillin can be used to the best advantage in the treatment of battle wounds. The simple answer is that penicillin treatment will overcome sepsis if it can be started within a fortnight of wounding or preferably earlier, that it should be accompanied wherever possible by complete closure, and that the prospects for it are improved by preliminary insufflation with penicillin-sulphanilamide powder in the forward area. Treatment at this stage, which is feasible at any advanced base, will be far more productive of results than any attack on chronic and intractable suppuration. The recommendation that penicillin treatment be mainly confined to one theatre of operations will be commended in so far as the study of a therapeutic problem is concerned. But to the extent that penicillin wound therapy becomes well-founded and capable of successful general application this restriction must appear in a different light, especially if larger supplies become available. We look forward to hearing that the supply position and the availability of trained personnel permit of extending this treatment if necessary to other possible theatres of war than the Mediterranean.

PERIPHERAL BLOOD VESSELS IN HEALTH AND DISEASE

Recent groups of papers published in America testify to the continued versatility of the attack on the problems presented by the peripheral vasculature. Complicated studies are being made with elaborate plethysmographs, calorimeters, oscillometers, capillary microscopes, and capillary manometers. On the other hand there are experiments involving the triple response of the small vessels of the skin, the injection of histamine, or the production of a saline wheal, which are technically so simple that they may be carried out by any clinician. It is a field full of questions awaiting answers, where it is easy to collect data, but where the interpretation of results is extremely difficult and where all experimental methods need to be controlled rigorously.

A new technique has been elaborated by Divalpa and his co-workers¹ from the reactive hyperaemia test, used widely in this country to separate organic from functional vascular disorders. In the "ring reactive hyperaemia test," as they call it, a 500-gramme lead weight with a lower surface whose area is 5 sq. cm. is placed on the skin for a sufficient time to cause a hyperaemic area of even intensity and discrete edges after removal. This is called the "threshold time," and is an indication of the ability of the smallest vessels of the skin to respond by reactive hyperaemia. The time taken for the hyperaemic area to fade to the colour of the surrounding skin is called the "clearing time," and is an indication of the rate of the local blood flow. Many factors apart from disease of the vessels affect the response. The activity of the patient, his environment, and his diet must all be standardized, and the speed of response varies even with the season. Both the "threshold time" and the "clearing time" are shorter in the cephalad segments than they are in caudal segments, and the palm, sole, cheek, and buttocks give values below the mean. In the aged there is little change on the trunk, but on the extremities both the times are lengthened. Some attempt was made to determine the cause of the changes. It was noted that the areas of greatest sensitivity are those where the concentration of haemoglobin is proportionally highest. Induced anoxaemia and acidosis were followed by decreased sensitivity, and alkalosis by an increase. Divalpa concluded that the irritability and the blood flow of the small cutaneous vessels are related to the concentration of CO₂ in the blood.²

Much work continues to be done on those diseases of the peripheral vessels which cause gross nutritional changes in the tissues. When arteriosclerosis is complicated by skin lesions on the feet the ability of the small vessels of the skin to dilate after ischaemia has been shown to be normal. As was to be expected, it was found that the blood flow is reduced, which suggests that the skin lesions are related to the rate of cutaneous blood flow and not to a change in the functional capacity of the small vessels finally responsible for the nutrition of the tissues.^{3,4} The digital circulation in Raynaud's disease, scleroderma, and thrombo-

angiitis obliterans has been studied in great detail with the aid of a calorimeter which makes possible an estimate of the rate of blood flow.⁵ In Raynaud's disease and in scleroderma the digital blood flow is usually decreased and the vascular resistance increased. In thrombo-angiitis obliterans the vascular resistance is normal, but the blood flow is decreased because of the low digital pressure. The results confirm the views generally held about these conditions and lead to a clearer understanding of the functional changes involved. For clinical purposes little information is obtained from complicated investigations in clear-cut cases of organic obliterative disease of the arteries except as supporting evidence. The physician can obtain the information necessary for his diagnosis by observing the nutrition and colour of the skin, by palpating the arteries, and by measuring the temperature with the back of his hand.

The dynamics of the circulation in hypertension attract much attention. Eichna and Bordley⁶ have not been content with the indirect evidence that there is no change in the pressure in the capillaries in hypertension and have proved it by direct micro-injection. The first part of their report,⁷ which deals with the effect on capillary blood pressure of such factors as neurogenic vasoconstriction, vasoconstriction with adrenaline, and reflex vasodilatation, is a good indication of the amount of work to be done in this field before you can begin to answer your original question. Another group of workers have measured the speed and degree of the response of the small vessels which follows sensory stimuli such as pin-prick.⁸ The data suggest that in cases of hypertension the reaction time of the vessels is short and the degree of constriction greater than in normal subjects. This is, of course, merely a more elaborate way of getting at the same point reached by Hines and Brown,⁹ who measured the increase in blood pressure after putting the hand in iced water. Brown and Macgrath demonstrated a similar increase in the reactivity of the blood vessels of animals after the experimental production of hypertension.¹⁰ The digital blood flow in hypertension has again been measured,¹¹ this time with a calorimeter, and in essential benign hypertension it is normal. In malignant hypertension it is decreased, and the vascular resistance is increased out of proportion to the elevation of blood pressure. There is another difference between the two conditions: in benign hypertension there is a normal response to the "ring reactive hyperaemia test," but in malignant hypertension the sensitivity of the smallest vessels of the skin is greatly reduced.⁴ As so often happens with a new observation, we are reminded of an old one, made more simply, and this time it is Volhard's separation of hypertensive patients into those with red and those with pale skins. Perhaps here was a lead which has been neglected because the original interpretation proved to be wrong. Now we can expect new attempts to explain the nature of this long-known difference, and there is reason to hope that they will rapidly have clinical importance.

TREATMENT OF FACIAL PALSY

The recommendation of Ballance and Duel, based on experimental and clinical grounds, that every case of facial palsy should be submitted to operation as soon as possible has yielded a large harvest of good results. But as many cases recover spontaneously their advice has not always proved acceptable. Unfortunately the hope of recovery leads not only to delay, but to such long delay that good recovery in any circumstances is improbable. They stated—perhaps too dogmatically—that “the accepted time to operate is now. No delay is justifiable.” In fact, however, it has never been possible to distinguish those cases which will recover without operation from those which will not, apart from those in which it is known that the nerve has been either cut or torn, making recovery impossible without some form of surgical intervention. It was, however, the disastrous result of waiting too long for recovery which never came that led Ballance and Duel into the recommendation that all cases should be submitted to immediate operation.

In the hope of obtaining some information in the matter of prognosis which would resolve this difficulty in the selection of cases for operation, Karsten Kettel¹ (Copenhagen) re-examined a large number of patients suffering from facial palsy from the clinical material treated at the Municipal Hospital in Copenhagen between 1906 and 1938. Among 13,135 cases of suppuration in the middle ear there occurred 264 cases of peripheral facial palsy. None of the patients was under observation for less than a year, and 35 were observed for over twenty years. Many had died and some could not be traced, but it was possible to re-examine 169. Some of the conclusions at which it was justifiable to arrive were as follows: After three years, normal sense of taste on the affected side becomes restored even after a radical mastoid operation. This is ascribed to the possibility that the opposite chorda tympani or the glossopharyngeal on the same side can take over the function of taste, as regeneration of the chorda tympani must be impossible. The proportion of patients with facial palsy is about 2% of all cases of otitis media, both acute and chronic, and this agrees closely with many other statistical observations; but facial palsy is a much commoner complication of chronic than of acute otitis media, this being due chiefly to the distinctive influence of cholesteatoma. Post-operative facial paralysis is also much commoner after chronic than after acute otitis media. This follows from the nature of the operations required, the radical operation and labyrinth operations carrying greater risks. In acute otitis of the mastoid it is impossible to predict a more favourable result in partial than in complete paralysis, but in the great majority of cases the palsy disappears after operation, without any decompression of the nerve by opening the Fallopian canal. However, if the palsy does not disappear the patient must be kept under observation. Not only is chronic otitis media an absolute indication for the radical operation in facial palsy, in contrast to the relative indication only in acute otitis, but the prognosis is not nearly so good. In about half of these cases there was either no recovery at all, or very little. The test for faradic excitability does not provide any useful information in forming a prognosis. It is noted that a partial paralysis which followed fracture of the posterior wall of the external auditory meatus still persisted 24 years later. In sixty patients in whom facial palsy supervened immediately on either the radical operation or the radical combined with the labyrinthine operation, the recovery was either quite negligible or unsatisfactory in 37; in 6 the paralysis was slight; and in only 17 was there full recovery.

¹ Arch. Otolaryngol., 1943, 37, 303.

The author concludes that these last bad results might be improved if the advice of Ballance and Duel to reopen the wound immediately were followed, with the object either of decompressing the nerve in its canal or of grafting the gap in a severed nerve. It is possible that some unnecessary operations would be performed, but on the whole the results would be better. Actually, it is quite evident that if the nerve is known to have been divided or torn and the central end is accessible, the sooner the wound is reopened and a graft inserted the more likely is there to be good recovery without contracture. When there is no breach of continuity the benefit of simply exposing the nerve trunk is not so clear, but recovery from haematoma in the canal or swelling caused by bruising is no doubt accelerated. The results of grafting the gap in a torn or severed nerve have been on the whole satisfactory, though the results are not always entirely satisfactory on account of contractures, synkinesia (the whole of the facial musculature contracting together), and occasionally ties. Accessibility of the central end is a necessary assumption which Ballance and Duel ignored, but this condition is not infrequently absent, in which case resort to the older method of uniting the facial with the hypoglossal is necessary. This does not restore the emotional movements to the face, but it apparently possesses the advantage that it is not followed by either contracture or tie.

BILL OF HEALTH FOR TWO GREAT CITIES

Liverpool and Manchester, the third and fourth cities of England in population, and separated from one another by only 35 miles of Lancashire country, show very similar health records. Liverpool has the advantage in the birth rate (20.5 per 1,000 as against Manchester's 17.0), but the death rate is almost identical for 1942 (14.0 and 14.7). In infant mortality Manchester had the better record last year (64.5 per 1,000 births as compared with Liverpool's 76.0), but the maternal mortality rates (round about 2.3) were almost exactly the same in the two cities. Both showed a fall in mortality from tuberculosis; in Manchester this came down to 1.12 per 1,000 of population and in Liverpool to 1.15, but the notifications in Liverpool were slightly up on the previous year, and in Manchester slightly down. Other figures in the reports for 1942 from the medical officers of health show the extent of inoculation against diphtheria. In Manchester to the end of last year 17,707 children under 5 had had a full course of injections, 29,575 children between 5 and 10, and 38,483 between 10 and 15. The figures for these three age groups in Liverpool were respectively 15,337, 28,824, and 35,758, but Liverpool has an estimated total population some 68,000 higher than Manchester, and presumably a higher child population also. In both cities the story of venereal disease is much the same as in London. The medical officer of health for Liverpool mentions that early syphilis appears to have increased four times in the male and eight times in the female population since 1938, and in Manchester, comparing 1942 with 1939, there has been a decrease in new cases of venereal disease among males of 13%, but an increase among females of 28.7%. But, of course, these sex ratios are fallacious, because the figures relate only to civilians, and the true extent of any real increase is not reflected in clinic records. Both these reports indicate the activity and vigilance of the public health departments, especially in maternity and child welfare, sanitary administration, and hospital service. The medical officer of health for Manchester says that the hospital services are ripe for co-ordination, reconstruction, and fresh building. The large and important hospitals controlled by the city council

are providing excellent service, but much devotion is required of the medical and nursing staffs to cope with the disadvantages and difficulties of the many unsatisfactory buildings inherited as the result of transfer of hospital functions. Finally, it should be noted that in neither city in the fourth year of war was there a case of plague, of smallpox, or of typhus fever, and the number of notifications of enteric could almost be counted on the fingers.

OESTROGENS AND VAGINAL GLYCOGEN

As a result of numerous experiments, in which Papanicolaou and his colleagues^{1,2,3} played a leading part, examination of the vaginal smears of laboratory animals, and later of women, has been widely used to indicate the approximate amount of oestrogen in circulation and to control oestrogen therapy, though its practical value has been questioned by some. Besides showing a change in cell type, the vaginal epithelium reacts to oestrogens by increasing its glycogen content, the amount of glycogen being directly proportional to the oestrogen stimulus. Thus in the newly born child the vaginal cells contain some glycogen owing to the influence of maternal oestrogen during intra-uterine life. After birth the glycogen quickly disappears, to reappear at pre-pubertal age. During the years of sexual activity the vagina is rich in glycogen, especially during pregnancy. After the menopause the deposit of glycogen wanes, though it persists for a variable period in different women, according to the rate at which the secretion of oestrogen falls off.

Evidence suggests that the vaginal glycogen content is a more accurate indicator of oestrogen stimulation than is the type of epithelial cell, and so vaginal glycogen studies rather than vaginal smears have recently been used in the diagnosis of oestrogen deficiency. Several methods are described—removal of small portions of vaginal epithelium with a punch and staining sections with iodine; addition of a standard amount of Lugol's iodine to the previously collected vaginal discharge; and application of Lugol's iodine direct to the vaginal walls. In all cases the intensity of the brown coloration produced is used as a guide to the amount of oestrogen in circulation. Mack⁴ now reports another technique; this consists in making a vaginal smear and then suspending it over a dish of Lugol's iodine. The staining from the iodine vapour is proportional to the glycogen content of the epithelial cells; four grades of reaction are described. Mack has employed this method not only to indicate oestrogen insufficiency but also to compare the results of the various oestrogens in therapy, and to assess the dose required to yield the full glycogen response. His results confirm that glycogen often persists in the vaginal epithelium many years after the menopause. Whether the oestrogen responsible for this continues to come from the ovary, or from other sources such as the adrenals, is unknown; but Mack suggests that the ovary is probably the source, for the glycogen disappears more quickly and constantly after a surgical than after a natural menopause. But this test for oestrogen sufficiency or deficiency suffers the same disadvantage as all indirect methods of oestrogen assay. It depends on the hormone in circulation being in a biologically active form, and also on the ability of the tissue reagent to react to the hormone stimulus; and the tissues are not always able to do this. Thus in the presence of local infection, such as trichomonal vaginitis, Mack found that the glycogen content of the epithelium was

unaffected by oestrogen administration. Similarly, in debilitated patients suffering from tuberculosis or other general diseases vaginal glycopenia, like amenorrhoea, is common and persists in spite of oestrogen therapy. This is particularly true in febrile conditions. It has usually been suggested that such conditions have this effect on the genital organs because they suppress the secretion of oestrogen. But Mack's results go to show that toxic factors, and especially fever, do not necessarily inhibit ovarian activity, but act rather as "antihormones" and render the oestrogen biologically inactive or, maybe, even destroy it. Constitutional disease might also prevent the mobilization of glycogen by oestrogen.

Such conjectures raise interesting possibilities. In the meantime this simple and rapid iodine vapour test, with its acknowledged limitations, and demanding a certain amount of experience to interpret the reactions, should be of value to those who undertake oestrogen therapy.

TOXOPLASMA IN MAN

Human toxoplasmosis was first identified in America in a case of infantile encephalomyelitis by A. Wolf, D. Cowen, and B. H. Paige,¹ when the protozoon was transmitted to laboratory animals. It has since been recognized as the cause of a milder encephalitis in older children,² and of pulmonary disease in adults.³ Because of the diagnostic importance of chorioretinitis in this disease a full and illustrated account of the ophthalmoscopic range of variation in the lesions found in nine cases has been recorded by F. L. P. Koch *et al.*⁴ The histological basis of these clinical findings is also provided from material obtained at necropsy in four of the cases. Ophthalmoscopically the lesions are focal, bilateral, and often multiple. The macular region is almost invariably involved, but more peripheral lesions are often present, while the remaining portions of the retina and the "vasculature" are normal. The vitreous in all but one case was found to remain clear. The toxoplasmic infection, which takes place during foetal life in the infantile cases, first excites focal oedema, inflammation, and necrosis in the retina and adjacent choroid. This is succeeded by a granulomatous reaction with disorganization of normal structure. The protozoon was identified in these lesions but was rarely found in the choroid. Neutralization tests in rabbits with selected human sera suggest that toxoplasmosis may be more widespread, at all events in North America, than is generally supposed. Thus Sabin⁵ has found that in children with a combination of hydrocephalus or microcephaly, cerebral calcification, and chorioretinitis involving the macular region, a positive reaction was obtained in 10 out of 13 cases and in 8 out of 10 of their mothers. But if cerebral calcification and chorioretinitis were lacking the antibodies were absent. A high proportion of positive tests was also obtained in both older children and adults with chorioretinitis of unknown aetiology but resembling that of toxoplasmosis.

We have yet to learn how this disease is acquired by human beings, and by what means it may be treated. So far, however, it has been found⁶ that sulphathiazole will hold the infection in check in the mouse if the drug is given within five days of inoculation and then maintained. Since the protozoon is of intracellular habit this observation raises an interesting question concerning the mode of action of this drug in such circumstances.

POSSIBLE DEVELOPMENTS IN SOCIAL MEDICINE*

BY

JOHN PEMBERTON, M.D., M.R.C.P.

Medical First Assistant and Medical Tutor, Royal Hospital, Sheffield

The war, by increasing the interdependence of each member of the community, has stimulated the development of new social concepts and experiments. The widespread interest of the medical profession in social medicine is symptomatic of this new impulse, and has already been made into a potent force by the inauguration of departments of social medicine in the universities of Oxford and Birmingham.

It has been customary in the past to accept as a working hypothesis the belief that most diseases have a single and specific cause. This belief was fostered by the discovery of bacteria and the demonstration of their specific relation to certain diseases, and was fortified by the subsequent discovery of the specific immunity which often follows infection.

Social medicine extends the conception of aetiology beyond the immediate or specific cause to non-specific and often multiple causes—a point elaborated by Prof. Ryle in the Gilchrist lecture (1942). This conception may be applied to diseases which have a well-defined specific cause—for example, tuberculosis and typhoid—as well as to those with a more indefinite aetiology. It is true that the tubercle bacillus causes tuberculosis and the typhoid bacillus causes typhoid, but it is equally true, and of more practical use in preventing these diseases, to say that overcrowding and undernutrition cause tuberculosis, and that impure water supplies and contaminated foodstuffs cause typhoid.

In addition to these external environmental causes there are individual factors depending indirectly on the external environment. Not all of those who are bacteriologically susceptible to an infective disease will develop it. Other links which must be introduced into the aetiological chain are the subject's state of nutrition, the presence of excessive fatigue, and possibly other influences as yet unknown.

Pavlov (1910) described "equilibration with surrounding Nature" as the "fundamental law of life." It is the disturbance of this equilibrium between man and his environment which produces most physical and mental illness. In congenital and inherited disease the equilibrium is disturbed by agencies within the individual, independent of environmental influences. In most other diseases environmental defects play an important and often decisive part in overthrowing this balance which is health.

Claude Bernard referred to the blood and tissue fluids which bring nutrients to the various organs and remove the waste products as the *milieu intérieur*. The patient's external environment, which consists chiefly of his dwelling, his diet, the conditions of his work, the nature of his leisure, and his relations with his family and fellow men, might be called his *milieu extérieur*. It is the relation of disease to the *milieu intérieur* with which social medicine is concerned.

It would be wrong to assume that the advent of social medicine marks a revolution in medical thought or any break in the continuity of medical progress. What is implied by the new name is, I think, a shift of emphasis. Some doctors have always believed that much disease results from bad environmental conditions. Now many more doctors, perhaps the majority, have come to that conclusion.

Sir Wilson Jameson (1942) has shown how advances in social medicine are stimulated in wartime. The development of mass radiography, the expansion of the industrial health services and rehabilitation schemes, and the introduction of a food policy based on health needs have been accelerated by the stimulus of the urgent needs of war. But the facts on which these advances are based and which compel attention to the social aspects of disease were already established before the outbreak of war. Numerous authors had demonstrated the evil effects on health of an inadequate diet, overcrowding, and unhealthy conditions of work.

One of the most important publications in this country establishing the need for a social approach to the problem of disease is the report of the Registrar-General on Occupational Mortality (1938). This is the first occasion on which mortality rates have been given for different social classes as well as for different occupations, and also the first time that the mortality rates of wives grouped according to the occupation of the husband are given.

The report divides the population into five social classes on the basis of occupation as given in the 1931 census returns. The professions are placed in Class I, skilled workers in Class III, and unskilled workers in Class V, with two intermediate groups. The following facts from the report are among the most significant from the point of view of social medicine. The mortality rates of diseases of the respiratory system, ear and mastoid disease, valvular heart disease, and gastric and duodenal ulcer, and the infant mortality rate increase steadily as the social scale is descended, so that the rates are approximately twice as high in Class V as in Class I. In pregnancy and childbirth the death rate is 50% higher in Class V than in Class I, and in the second year of life the death rate in Class V is five times that of Class I.

The social distribution of some of the commoner forms of cancer is often overlooked, although this report demonstrates a definite relation between social grade and cancer of the "exposed" sites. Death rates from cancer of the tongue, tonsil, jaw, pharynx, oesophagus, stomach, larynx, skin, and uterus are approximately twice as high in Class V as in Class I. Possibly those in the higher occupational groups seek treatment earlier, but this factor can, however, have little effect on the mortality rates of cancer of the stomach, which is almost invariably fatal however early treatment is sought, and in cancer of the stomach there is a steep social gradient in the mortality rates.

The Registrar-General's report testifies to the existence of a mass of preventable disease of social origin. It raises many problems which would appear to be accessible to research in social medicine. It shows, for instance, that there are influences in the environment of the lower occupational groups which produce high mortality rates for all the principal respiratory diseases. What are these adverse factors and how can they be prevented? We know that overcrowding is an important factor in the production of tuberculosis, but we do not yet know for certain why steel workers suffer a high incidence of pneumonia (Registrar-General, 1938), nor what part dust and exposure play in the production of chronic bronchitis and emphysema. It has been shown by Middel Turner (1938) that cancer of the lung is significantly more common in foundry workers and metal workers than in the general population, and Argyll Campbell (1943) has proved that dusts encountered in the heavy metal industries produce a significant increase in the incidence of pulmonary tumours in mice. But the specific agent or agents responsible for the high rates of cancer of the lung or larynx in these industries have still to be established, and methods of prevention devised. The high death rate from valvular disease of the heart in the lower occupational groups is mainly due to the late results of rheumatic fever. Morris and Titmuss (1942) analysed the relation between rheumatic fever and environment, and concluded that rheumatic heart disease was due to some condition associated with poverty, not necessarily overcrowding. Mille (1942) gives evidence supporting the hypothesis that damp houses are the cause of juvenile rheumatism, while Glazebrook and Scott Thomson (1942) found that a supplement of vitamin C prevented the occurrence of cases of acute rheumatism in a group of 335 boys, whereas in a control group of 1,100 there were 16 cases. The problem of the aetiology of acute rheumatism still awaits a complete solution, although it is now certain that environmental factors are of major importance. The infant mortality rate has long been recognized as an index of social conditions. Malnutrition, overcrowding, an infected food are important causes of high infantile mortality rates, but it is not accurately known how these causes operate and to what extent other factors are involved. These are few of the problems that confront social medicine; the list could be extended indefinitely.

* Received for publication July 12, 1943.

Social medicine appears to me to open two new doors in medical practice. The first leads to a new attitude to disease, and the second to a new technique for its conquest. I think that one of the first questions a medical student should be trained to ask himself when confronted with a sick person is, "To what extent has this patient's environment contributed to the aetiology of his disease?" and when the diagnosis has been made, "To what extent will the treatment and prognosis in this case be influenced by environmental conditions when he leaves the hospital?" Because it is a new way of looking at disease it should not become a special branch, but should be welded into the clinical curriculum at all points. Above all, it should not be excluded from the stimulating and vitalizing influence of bedside medicine.

The new technique which social medicine offers is one for an extended study of aetiology. If the maximal results are to be obtained a definite method is desirable. Such a study might consist of the following five stages:

1. An inspection of the vital statistics relating to the aetiological problem under consideration. A possible cause of a high disease rate may be suggested by statistical evidence, but this can only be proved or disproved by a close study of individual cases.

2. The "trace-back" stage, consisting of a detailed study of individual cases of the disease in question with special reference to a detailed environmental history checked by personal observation of the patient's *milieu extérieur*.

3. A survey of an adequate sample of the population exposed to the environmental conditions under suspicion, together with a control group not so exposed. A number of latent or early cases of the disease might be discovered in the exposed group at this stage.

4. An attempt to reproduce the condition in experimental animals.

5. The last stage, in which the hypothesis would be proved or disproved, would consist of modifying the environment of an exposed group of the population by removing or neutralizing the suspected adverse characteristics and noting the effect on the incidence of the disease in question.

The individual worker would find it difficult, if not impossible, to complete such an investigation alone. The collaboration of hospital and domiciliary doctors, research workers, statisticians, nutrition workers, sanitary inspectors, social workers, inspectors of factories, works managers, public health doctors, and local authorities might all be required to carry through to a successful conclusion an experiment of this sort. The human element and the diversity of types and conditions encountered might at times baulk and confuse the inquirer, who would find that there were more variables than he could at first control, but I do not believe the difficulties are insuperable. Moreover, the integration of the medical services, to which we can now look forward with confidence, will facilitate the search for the sources of disease by bringing together in one organization workers in curative and preventive medicine.

BLIND PHYSIOTHERAPISTS

The school of massage for blind men and women, established by the National Institute for the Blind in 1915, is to be enlarged. It will remain in the same building as the Eichholz Clinic in Great Portland Street, London, where another of the extensive floors is to be added to the school premises. During its career the school has undergone sundry changes, but all have been in the cause of progress. As the only training centre in the world exclusively for sightless physiotherapists, the Institute has regarded it a point of honour to maintain a high degree of efficiency, a policy that has established the blind masseur as second to none in the profession. One reason for enlarging the school is the proved success of the "educated" blind and the increase in this category brought about by the growing number of young people passing through the National Insti-

tute's two public schools, Worcester College for blind boys, and Chorleywood College for girls with little or no sight. Worcester was much enlarged shortly before the outbreak of war, but already it is filled to capacity; Chorleywood also is nearing the point where more accommodation will be needed for myopic girls eligible for secondary education. Beyond these sources of potential students for the massage school, account must be taken of blinded war casualties in the fighting Services and civilian population, among whom are bound to be many persons desirous of, and suitable for, training. A matter to which full attention must be given is the demand of the profession itself. The blind practitioner cannot lag behind the advancing technique, and the curriculum at the school must be adjusted accordingly. The present two-year course puts severe pressure on the students, and a longer course will probably have to be introduced soon. It is to meet the challenge of modern developments and to help more young blind persons of ability that the National Institute has decided to embark on the extension scheme.

THE TREATMENT OF WAR WOUNDS WITH PENICILLIN

The following is an account written for us by Prof. L. P. Garrod of a report published by the War Office entitled, "A Preliminary Report to the War Office and the Medical Research Council on Investigations concerning the Use of Penicillin in War Wounds—Carried out under the Direction of Prof. H. W. Florey, F.R.S., and Brig. Hugh Cairns, F.R.C.S., R.A.M.C." This report is for official use only, but we are permitted to publish an abstract of its contents.

This printed report of 114 pages is in two parts: a general account of the investigation and its results by Florey and Cairns, and 12 detailed descriptions of particular classes of case by individual surgeons, including numerous fairly full case histories. The work described was carried out in North Africa during a period of only 3 months last summer, in order to ascertain as quickly as possible how penicillin can be used to the best advantage in treating battle wounds. The best use of very limited supplies involved discovering how to obtain good results by local treatment only, since this is far more economical than systemic administration. No attempt was made deliberately to compare penicillin treatment with any other—a much more formidable project.

Methods of Administration

Penicillin was applied locally either as a solution in distilled water containing 250 units of calcium penicillin per c.cm., as a powder in which calcium penicillin was diluted with sulphamilamide to give a strength of 500, 2,000, or 5,000 units per g. (in a few cases it was used undiluted), or as a cream in a lanette wax base. Systemic treatment was achieved by intramuscular or intravenous injection of sodium penicillin by continuous drip in glucose saline, the daily dose being usually 120,000 units: owing to impurities in some of the batches used injection by the former route caused pain and by the latter febrile reactions and early venous thrombosis. There were no serious toxic effects. A good plan was to give intramuscular injections for 1 day after operation, then start on intravenous drip, and revert to intramuscular injections later if necessary. Some loss of potency occurred, especially in calcium penicillin, owing to climatic conditions and transport: doses stated are therefore maxima and the probable true dose was up to 30% less.

Chronic Wound Sepsis

The first phase of the investigation was the treatment in Algiers by Lieut.-Col. Ian Fraser of a series of septic wounds from 3 weeks to 4 months old. These cases were accommodated in a special 30-bed ward, and full bacteriological control was carried out by Major Scott Thomson. Local treatment with solution, powder, and cream was disappointing: accessible surfaces could be sterilized, but deep-seated infection could not be controlled. Systemic administration was resorted to in 8 cases of septic compound fracture, 4 of which received over 1,000,000 units; this lavish treatment cleared up the infection in 6.

It was concluded from this experience that long-standing sepsis with loculated abscesses and poor general condition was a relatively unpromising field, and that cases should be treated earlier. Almost ideal arrangements for this were possible when the campaign in Sicily opened. Lieut.-Col. Fraser and

Major MacLennan (bacteriologist) proceeded to Sicily, where they examined casualties early and gave preliminary treatment: the men were then evacuated to Tripoli or Sousse, where 10 surgeons in 5 general hospitals who took part in the investigation worked in collaboration with Florey and Cairns. The cases treated were of 2 principal classes.

Recent Soft-tissue Wounds

Of these there were 171, of which 53 were treated by Lieut.-Col. J. S. Jeffrey: they were mostly from 3 to 12 days old (extremes 12 hours and 22 days), and the majority were infected. "... in fact some were purulent and most were clinically dirty. No case was rejected for this reason, and the wounds were closed before the results of the preliminary bacteriological examination were known." Large and difficult wounds were chosen, including 25 of the buttock: 7 cases were amputation stumps. The policy adopted was immediate closure, relying on penicillin applied locally to hold infection in check. The principal method of application was through tubes inserted at the operation for suture. One or more 1/8-in. rubber tubes were introduced through stab holes or through the wound itself, the outer ends projecting beyond the dressing, and through these from 3 to 10 c.cm. of penicillin solution (250 units per c.cm.) was injected twice daily for 4 days. Some cases were also treated by insufflation of powder, either as a preliminary measure in the forward area (which according to Scott Thomson's bacteriological data reduced the frequency of infection with pyogenic cocci on arrival at the forward base from 57 to 26%) or at the base for 3 days before closure was undertaken: powder alone with no irrigation after closure was used in exceptionally clean cases. Complete union was secured in 104 cases, subtotal union—i.e., healing by granulation in some part of the wound—in 60; failures numbered 7. These wounds show little reaction: they may remain dry or discharge "a thin salmon-pink purulent fluid" which turns green on the dressing—this is "Gram-negative pus" containing *Ps. pyocyanea*, and healing proceeds rapidly in spite of its formation. The results as a whole were such that Jeffrey goes so far as to say: "With penicillin the obstacle of infection has been practically overcome," and it is estimated that from 3 to 6 weeks in hospital is saved. Causes of failure or subtotal union were: stitching up so tightly in layers that the solution could not penetrate the whole of the wound; placing sutures too near the skin edge; removing sutures too soon; injecting too much solution (3 c.cm. per tube was found better than 10 c.cm.), since this tended to separate the wound surfaces; and relying alone on powder before suture when this tends to be washed away by blood. The main difficulty in applying this treatment was caused by unduly drastic wound excision in the forward area: it is very strongly emphasized that this should be conservative, skin especially being spared. It is also stated emphatically that suture should not be attempted in the C.C.S., and that at the forward base where it is undertaken the man should remain until healing is complete.

Recent Fractures

A different method was adopted for compound fractures. Of these 36 of these cases, mostly severe comminuted fractures of long bones: they were 5 to 14 days old on arrival at the forward base; 9 had been treated locally with penicillin-sulphanilamide powder and 27 with sulphanilamide only. The aim was to convert to a simple fracture by closure and so prevent chronic infection, and systemic treatment was considered necessary: the standard course was 100,000 units daily (by the 3-hourly intramuscular or continuous intravenous route) for 5 days. Only 31 of the wounds were capable of being sutured: complete union was achieved in 16, subtotal in 10, and there were 5 failures. Of the 6 cases not sutured, 5 healed by granulation rapidly without infection and 1 died of fat embolism. Fractures of the femur gave the worst results, and it is advocated that in future systemic treatment for these should be continued for 7 to 10 days. Inadequate dosage was apparently the main cause of failure, and bacteriological studies showed that pyogenic cocci sometimes persisted after the full course. Closure was too ambitious in some of the large wounds, where drainage even for Gram-negative pus would have been preferable. There were also 2 examples of infection by penicillin-resistant cocci.

Miscellaneous Infections

Smaller numbers of cases were treated in the following categories:

Gas Gangrene.—It was not often possible to get these cases to the forward base before they were moribund, but 7 cases were treated, of which complete histories are given. It is pointed out that the treatment should include full doses of antitoxin to combat the toxæmia, and the excision of all dead tissue, since penicillin cannot reach this. Systemic administration for 3 to 5 days is advocated: local application is useless in treatment, although it may be of great value for prevention. The infection was apparently checked in 4 cases: 3 died from causes apparently outside the control of penicillin.

Head Wounds.—Brain wounds 3 to 12 days old, almost all infected with pyogenic organisms, were excised, cleaned, and closed: a small tube was passed through a stab hole into the brain cavity, and pus was aspirated and solution injected twice daily for 3 to 6 days. Of 23 cases only 3 died—2 of intracranial infection. These results, so far as they go, compare very favourably with those obtained by other methods. Most non-penetrating wounds of the skull and scalp were treated by a single application of powder at the time of suture.

Undiluted Powder and Primary Suture.—During the first 2 days of the Sicilian invasion 13 casualties with wound involving bones or joints in nearly all cases and averaging 40 hours old were operated on in a hospital ship off-shore. About 1 g. (50,000 units) of undiluted calcium penicillin powder was applied by spoon and rubbed into all parts of the wound, which was then closed. Results, so far as they are known, were excellent, but after-histories are not all available.

Some cases of burns were treated by insufflation with "1% penicillin in sulphonamide powder": haemolytic streptococcal infection was thus eliminated which had resisted other treatments. One recent and 9 sulphonamide-resistant cases of gonorrhoea were given not more than 12 4-hourly intramuscular injections of 15,000 units, the effect of which was "like turning off a tap": no relapse was observed during 2 to 4 weeks subsequent observation. (Sulphonamide-resistant gonorrhoea is common in N. Africa, possibly because French M.O.s in charge of brothels give small doses of sulphonamides to prostitute as a prophylactic. The penicillin treatment of gonorrhoea should be restricted at present to highly trained fighting troops such as parachutists, in forward areas.)

Future Policy

Evidence has been obtained that "penicillin can make a substantial contribution to the health of wounded soldiers, with corresponding saving of hospital time." Plans for its use should assume that an average of 750,000 units of sodium penicillin per case is required for systemic treatment and 50,000 units of calcium salt for local. For the time being supplies should be under the control of the Directorate of Pathology at the War Office, and its use "should be mainly concentrated in one theatre of operations." Surgical and pathological penicillin officers should be in charge of treatment, which should be confined to predetermined types of case. The most hopeful field is the early treatment of soft-tissue wounds and fractures. Further experience should lead to improvements in technique, and only when the best method have been defined should a comparison be made with form of treatment not employing penicillin. The appointment of a statistical officer is recommended, to supervise accurate record keeping and a careful follow-up and to assess results. Similar information from an Army group not using penicillin would be valuable: there is an extreme dearth of accurate information about the frequency and duration of sepsis in battle wound and the effects of other measures such as sulphonamide treatment. Among other types of case, gas gangrene requires further study, and penetrating wounds of the chest, which have hitherto been excluded, should be studied particularly with a view to discovering whether pyogenic coccal infection can be controlled by the more economical method of local application.

"There can be little doubt that the prevention of infection with pyogenic cocci or its control in war wounds is within reach, and no criticism with its emphasis on difficulties should be allowed to stand in the way of the attainment of this ideal."

Reports of Societies

EPIDEMIC HEPATITIS: RECENT FIELD INVESTIGATIONS

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on Nov. 26, Dr. J. A. BRINCKER presiding, the subject for discussion was epidemic hepatitis. The CHAIRMAN reminded the meeting that jaundice had shown a steep and rapid rise during the last two years in this country, Europe, and North Africa. The Medical Research Council had appointed a committee on the subject, but its conclusions were not yet available. The present discussion would be confined to field work.

Dr. A. A. LISNEY, Deputy Medical Officer of Health for Leicestershire, said that during the past eight years he had collected 1,017 case records of patients in his county who had developed epidemic hepatitis. The first epidemic to come under his notice was in 1936 (there was an earlier one, recorded in the literature, with 45 cases, in 1933). Another epidemic occurred in 1937-8, a third (without so high a peak) in 1938-9, a fourth in 1941-2, and a fifth in 1942-3. In the last of these the total number of cases in one month reached the high level of 132. Only an isolated case appeared in the interval between the early part of 1939 and 1941. During the last epidemic a number of cases also occurred in the city of Leicester (which was not included in his survey), and there were three deaths—two children and one adult—between Oct. 28 and Nov. 14, 1942.

It had been easy to trace the case-to-case spread of the disease. There were a number of mild, abortive, or atypical cases which did not seem to come to anything. The majority of the cases occurred in children; the age group with the highest incidence was 5-10. The disease did not seem to attack the same village twice over, except for a case or two. There were two distinct types of local outbreak in the villages. For example, in Barlestone 49 cases were grouped in a period of less than four months, and at Burbage 84 within six months, but at Shepshed 30 cases were spread out over eleven months, and the same at Sileby and other places. There was no evidence of the disease being spread by means of milk, water, food, or vermin. It was evidently case-to-case spread, probably by droplet infection. The period of infectivity before jaundice appeared was at least a week, and once the jaundice appeared the infectivity ceased. Coryza was a very common symptom, and, except in the first epidemic, when it did not appear, was found in 39% of the cases. Sore throat was a common factor in three of the epidemics. Rash, mostly urticarial, but in a few cases petechial, was seen. There were three deaths, and there was circumstantial evidence of death in two other cases, but these persons had gone outside the county and could not be followed up. An endeavour had been made, by the collection of nasal washings, faecal material, etc., to isolate the organism, but without success. Complications were very rare. In the cases under review Dr. Lisney could record two cases in which diabetes followed almost immediately an attack of infective hepatitis and three others in which intermittent glycosuria had persisted since. Chronic pancreatitis was noted in one of the fatal cases during an exploratory laparotomy.

Infective Hepatitis in North Africa

Dr. E. T. C. SPOONER, Director of the Emergency Medical (Laboratory) Service at Cambridge, brought forward some collected results from different observers of the occurrence of epidemic hepatitis in the Middle East in 1942. It was stated that during the El Alamein battle the hospital sick admissions were about 50% higher than the battle casualty admissions, and a large proportion of this sickness was due to infective hepatitis. The events of the two previous years and the record of the last war made it possible to predict the occurrence of the 1942 epidemic, although no one could have foreseen that its magnitude would have been so great. The case rate per 1,000 during December for British and Dominion troops reached the high figure of 9. The brunt of the Middle East epidemic was borne by the Eighth Army, which accounted for about one-fourth of the total cases.

Officers were about 4.7 times as prone to infection as other ranks. It appeared from studying the dispositions of the troops that a period of residence in the El Alamein line might be the predisposing cause of the epidemic. Those regiments which spent the longest time in that region were the most heavily hit. It was difficult to explain on the basis of case-to-case spread and the usually accepted incubation period of about one month how the epidemic in an isolated unit could rise to a maximum and fade out again within five or six weeks, as it sometimes did.

The Indian troops and the Maoris, although both occasionally developed jaundice, were much less frequently affected than Europeans. No insect vectors could be incriminated, and there were no grounds for suspecting any, except that flies were particularly abundant in El Alamein in October and November. Two observations seemed to cast some doubt on the hypothesis of droplet infection. One was that among the crews of vehicles, who had to live, travel, feed, and sleep together, there did not seem to be any special tendency for more than one case to arise in any one vehicle. In a field regiment in which there were 59 cases altogether there were eight instances of more than one case occurring in the crew of one vehicle, but in most of these the time interval between the onset of the cases in the same vehicle was a little less or a little more than a week. The other observation was that the disease showed curiously little tendency to spread from prisoners of war captured in November, among whom jaundice was rife, to others who shared the same camps and who had been captured in the previous spring or summer.

Other Experiences

Squad. Ldr. DALMADY said that R.A.F. experience bore out the point that a larger proportion of officers than men was affected. Major CHUTE suggested that this might have something to do with the different feeding habits of the respective ranks. Officers, even during active operations, had their meals in common, whereas the men kept their own individual utensils. Dr. ELI DAVIS mentioned 29 cases which found their way into hospital and were fairly spread over the twelve months from October, 1942, to October of this year. Three of them had been sent in as cases of acute appendicitis. All were in children or young adults. They included three pairs of siblings. One nurse who was treating jaundice cases developed the disease. One boy had acholuric jaundice, for which splenectomy was done, and he recovered, but two of his cousins developed infective hepatitis during the epidemic. Dr. J. C. FORD spoke of an observation of 300 cases in the borough of Wembley in the autumn of last year. The cases spread across the borough at the same rate as measles and chicken-pox. There was a rise in October and a peak in January. At one particular school there were 78 cases of infective hepatitis out of 778 children on the register. Dr. NEWMAN described a small outbreak which had affected a day nursery. The curious point was that it was the attendants who were attacked, and not, to any large extent, the children. The outbreak illustrated the part played by healthy people in spreading the disease. Dr. W. H. BRADLEY mentioned Hallgren's finding (*Journal*, Nov. 27, p. 681) that the infection was water-borne, but Dr. LISNEY said that water supply could be excluded from the Leicestershire cases, and other speakers who had given their experiences agreed that the water could not be incriminated.

ADVANCES IN ORTHOPAEDICS

In his presidential address at the recent annual meeting of the British Orthopaedic Association Mr. G. R. GIRDLESTONE discussed the philosophic and practical considerations which marked the development of orthopaedics and the manner in which it had influenced the treatment of fractures in this country. There were still few general hospitals, he said, with a good accident service, although the case for it had been proved. Some hospitals were quite blind to their shortcomings. Members of the association must be guides and see to it that safe and simple methods were taught, and that, for example, splintage provided freedom from pain, freedom from pins, freedom of the circulation and freedom for its subsequent expansion. Familiarity with the ways of living tissues and the study of the bad end-results of trauma revealed that

the great majority of the latter were due to lack of knowledge, of dexterity, of gentleness, and of sustained interest in the after-care. The strength of the association and of its influence was in the regular meetings of a society of friends, eager to talk "shop" and exchange ideas, to travel widely to see the work of other men at home and abroad, to discuss freely in a spirit of mutual understanding and good will, seeking the truth without fear of offending one another, showing failures and confessing difficulties. Of orthopaedic hospitals he said their mercy must be very practical, but would only be effective if based on skill hardly won and generously given by men and women who had taken pains to acquire an intimate knowledge of their work and were unsparing of time and trouble.

Training, Resettlement, Rehabilitation

Mr. G. GOMME of the Ministry of Labour, reporting on the development of the Ministry's interim scheme for training and resettlement of the disabled, said 100,000 interviews with disabled workmen while in hospital had been completed. Broadly speaking, physical disability was not such a serious barrier to employment as had previously been thought. While 70% of those interviewed were back at work, it was open to question whether many of the wartime jobs arranged were suitable as permanent resettlement. The scheme had not yet been able to cope with that not inconsiderable group who for various reasons (usually psychological) were unemployable.

Mr. W. GISSANE, in describing the Birmingham experiment in accident treatment, referred to "rehabilitation shops" where the injured man could combine necessary treatment with productive work; it was hoped to provide a series to cover Birmingham. Here the hospital-surgeon was concerned with planning jobs and progress in movements, power, and duration of work. In the team also were the factory doctor and the shop manager—who was invaluable in making the work suitable for the more important activity of the factory in which the man was expected to earn his livelihood. The final stage was the direct transfer of the workman out of these shops back to the factory proper. The cycle of treatment was then complete. Major FRANK STINCHFIELD, U.S. Army, described the methods employed in that Army for the rehabilitation of the sick or injured soldier. A motion picture, prepared under the direction of Col. R. L. Diveley, showed the work of a special centre established for this purpose in Great Britain.

Some Orthopaedic Procedures

Major R. SOTO-HALL (U.S. Army Medical Corps) discussed lesions of the articular cartilage of the patella, which were found to have a high incidence scarcely noted in the Anglo-American literature. Fractures in the cartilage of the patella without bone involvement were common, and as a delayed manifestation was chondromalacia patellae. This was believed to be a form of aseptic necrosis and appeared as degeneration of the cartilage matrix. Many patients had little disability if the area involved was small. Of the operations—partial resection of abnormal cartilage, total resection of the articular surface, and patellectomy—the first-mentioned was useful only in small lesions, the second was unsatisfactory, but the third gave good results. He had performed it in five cases: four good or excellent results, the remaining one not improved. Patellectomy care must be taken to restore proper tension in the quadriceps expansion by overlapping the tendon. Major R. PATTERSON (U.S.A.M.C.) emphasized that in fractures of the upper end of the tibia involving the knee-joint excellent results could be obtained by conservative methods: aspiration of the haemarthrosis, reduction by compression or manipulation, and the institution of early motion, the next day passively and at about five days actively, in a Thomas splint with a Pierson attachment and traction. The improved control obtained by the incorporation of the patient's thigh and the upper part of the splint in plaster-of-Paris was also demonstrated.

Wing Comdr. W. D. COLTART, R.A.F., reviewed a series of injuries of the astragalus peculiar to airmen whose plane crashes. He emphasized the importance of complete reduction of the subastragaloid dislocation or subluxation which occurred in so many fractures of the neck of the talus. It was secured by plantar flexion, but might recur when this position was relieved at the end of the first month. Posterior dislocation

of the body was a surgical emergency, and should be reduced at once. The body should be preserved, if possible, even when, in late cases, avascular necrosis was present, for arthrodesis would give better results than astragalectomy, preserving the height of the foot and the leverage of the forefoot. If the whole bone or the body were irretrievable a second-stage fusion of the tibia to the os calcis should be planned. While deformity of the body following avascular necrosis rendered fusion inevitable, it had to be remembered that mere radiographic opacity without deformity could resolve if immobilization of the contiguous joints had been begun before opacity appeared and was continued long enough for regeneration to occur (this might take as long as 37 weeks).

Col. St. J. D. BUNTON, discussing gunshot wounds of the elbow-joint, reported upon 51 such injuries recorded by the M.E.F. during the third Libyan battle in the summer of 1942. Suppurative arthritis developed in 31, and amputation was necessary in two cases. There was no fracture in three elbows; there was severe bony damage in at least four out of every five patients, and the olecranon was injured in nearly half of all the elbows. There was evidence of injury to 16 peripheral nerves, of which 9 had recovered in four months or less; the fate of 2 was not known. He described the type of operation advisable in the forward and base areas, and stressed the advisability of leaving large bony fragments which had attachment, but of removing all small loose fragments lying around the fractured bones. The latter was important when an excision of the joint was performed. The indications for aspiration and delayed arthrotomy by posterior drainage were stated. The splinting employed was plaster-of-Paris, extending from the axilla to metacarpal necks, with the forearm supinated and wrist dorsiflexed. Large dirty wounds often improved by dressing through windows in the plaster two to three weeks after the wound, but usually the plaster was not changed for three weeks. Stiffness of the shoulder and hand was prevented by early active movement of these joints. The loss of the olecranon was not necessarily the cause of poor function. Recurrent osteomyelitis and sequestra formation were not a frequent sequel if the primary operation was well planned. Ankylosis was expected in 17 cases and flail elbows in 4.

Prof. H. J. SEDDON described the epidemic of poliomyelitis in Malta, to which reference was made in these columns on Nov. 27 (p. 657).

During the meeting it was announced that negotiation between the R.C.S. and the B.O.A. were well advanced for establishing the official headquarters of the association in premises of the College at Lincoln's Inn Fields. The advantage to British surgeons of the integration of this and other special branches of surgical science within the domain of the parent body were not least of the many desirable features of such an arrangement.

NUTRITIONAL RELIEF AFTER THE WAR

The scientific and medical aspects of nutritional relief after the war were discussed at a meeting of the Nutrition Society held on Nov. 6 at the London School of Hygiene and Tropical Medicine. Lord HORDER, who presided, opened with a brief review of the functions of the United Nations Relief and Rehabilitation Administration. He said there was a gap in the executive power of the Director-General, who, although empowered to collect food and commodities for export to countries needing relief, was not in a position to order the production of the necessary supplies. A Supreme Economic Council was obviously required. Another defect might possibly arise through inadequate planning for the transference of the responsibility for nutritional relief between the initial military government and U.N.R.R.A.

An Estimate of the Task

Prof. J. R. MARRACK said that the deficiency of food in Continental Europe at the end of 1918 was due much more to failure in production than to the lack of imports. The labour of men and animals was taken from the fields, artificial fertilizers were scarce, reduced crops led to destruction of animals and to further impoverishment of the soil through lack of manure. For the whole Continent cereal production was reduced by one-third; the reduction in livestock varied from 14% in France to over 70% in We Poland, and carcass weights were reduced even more on account of the leanness of the animals. In Germany milk production was only one-third of the pre-war level. Most of the relief was obtained

NUTRITIONAL RELIEF AFTER THE WAR

special credits granted by Governments, particularly that of the U.S.A., and this allowed the importation of some 4,000,000 tons of flour and grain, smaller amounts of pork products, and some miscellaneous and Army foods. The total imports by the official relief systems, which ended in September, 1919, were less than in a corresponding period before the war, and did not make good the deficit in the wheat harvest alone. Less food was supplied to Europe during the whole relief period than was imported into Great Britain in 1918, when our food imports were at their lowest level. Subsequent relief depended upon charity, and mainly took the form of canteen meals supplied to children who showed signs of malnutrition. At peak periods in April, 1920 and 1921, 34 and 24 million children were being fed. In Austria the meals supplied 660 calories, and contained only 5 g. of animal protein, the vitamins A and D of 60 ml. of fresh milk, and practically no vitamin C. A warning of what might happen if relief measures were inadequate was to be found in the famine in the U.S.S.R. in 1921-2, which caused 3,000,000 deaths through starvation and many more from indirect effects. The war also brought an alarming increase in juvenile tuberculosis in different parts of Europe.

It was estimated that the average normal consumer on the Continent was now receiving 1,400 calories a day, which meant a deficit of 600 calories. The deficiency varied from a consumption of 1,000 calories in Greece, Poland, and Spain to a consumption of almost completely adequate amounts in Germany. Slaughter of at least 10,000,000 cattle had led to a deficiency of meat, milk, cheese, and butter. The worst sufferers must be children over 5, because most of the milk was reserved for infants. The effects of the deficiency in first-class protein were found in an increased incidence of tuberculosis. Vitamin deficiencies were not universal: rickets was even less common in Belgium than formerly, due to the distribution of vitamin D, while the addition of vitamin A to margarine had reduced the risk of acute deficiency of potatoes, which also had a high yield of calories per acre. The use of flour of a high degree of extraction made deficiency of vitamin B unlikely except in areas where maize was used.

Surgeon-General EVANG pointed out that the power to allow or deny foodstuffs to occupied countries according to their value in the war effort was a most valuable weapon in Germany's hands, and it was questionable how far Prof. Marrack's estimates of caloric intakes were applicable to the more favoured regions. The criteria of undernutrition were difficult to define; in particular the significance of "hunger oedema" was puzzling, and its supposed relation to protein deficiency was obscured by its occurrence in Norway in persons receiving adequate amounts of good protein in the form of fish. In planning relief first consideration must be given to calories to be supplied as grain and fats. A valuable source of protein could be opened rapidly after the war by supplying fishing equipment to Norwegian seamen.

Dr. GEOFFREY H. BOURNE gave figures for the caloric values of the rations allowed in 1942 in different parts of Europe. Compared with a pre-war level of 3,000 calories the rations in Bohemia and Moravia provided 1,800 calories, in Norway 1,200, Denmark 1,400, Holland 1,800, Belgium 1,000, France 1,000, Serbia 1,200, Croatia 900, Greece 500; in Eastern Poland the Poles received 700 calories and Jews only 400, while in Western Poland the ration was about 1,000 calories. There was severe deprivation in occupied Russia. For the rest of Europe 1,000 to 1,500 calories could be taken as typical, with a tendency for malnutrition to be worse in towns.

How to Secure Relief

Dr. J. HAMMOND, discussing problems of production and relief, said the latter must be carried out in two stages. The first, which would raise nutrition to a level based on minimum requirements for life and health, must be realized in all countries before any one country started on the second phase, which aimed at raising the standard to optimum levels. The first minimum standards would be based on the rations now allowed in this country, but modified according to the pre-war food conditions and habits of the country concerned. Thus the number of calories required would vary from 900 for a child under 1 year to 4,200 for an adult male engaged in heavy work. Milk would be needed at the rate of 300 ml. daily for adolescents of 14 to 21 years old, and of 800 ml. daily for those 6 months to 3 years old and for expectant and nursing mothers. The annual allowance for adults in high-class proteins could be supplied as 30 kg. of meat, 76 kg. of milk, 4 kg. of cheese, 3 kg. of eggs, and 10 kg. of fish. As consumption of animal protein in Southern and Eastern Europe did not reach these levels even before the war, it would not be necessary to provide the full amounts, at least in the first stage.

There were two ways of supplying the relief: (1) by increased production in the country concerned; and (2) by importing food from overseas to make up the main deficiencies of the locally produced diet. Cereal crops in Europe to-day were probably 10% below their pre-war level, though high milling reduced the deficit so far as human requirements were concerned. Farm animals had probably decreased by about 25% in number. To increase crops in the

liberated countries fertilizers and machinery for deep ploughing must be supplied; these would need much less shipping space than the foodstuffs they produced. To get more milk dairy cows and others capable of reproduction should be preserved with the semen of their number increased by artificial fertilization with the semen of pedigree bulls. About three times as much land was needed to feed an individual on a diet rich in animal protein as on a mainly vegetarian diet. To satisfy immediate demands for meat adequate stocks should be accumulated now in canned or dehydrated form. The breeding of pigs and poultry should be started later, since some of their food was fit for direct human consumption. So far as British agriculture was concerned, cereal products would be needed for human consumption on the Continent and in the Far East, so that imported concentrated animal feeding stuffs would probably remain in short supply. For the same amount of fodder the yield of milk was much greater than the yield of meat; therefore available supplies should be mainly devoted to milk production. We should be prepared for a prolongation of the period of meat rationing.

The organization of relief in the Central Council for Refugees. The Russell, medical director to the organization, said it was highly desirable to improve morale to combine relief with a resumption so far as possible of public services. In Spain, where in 1938 the available diet contained only 1,000 calories, the relief organization distributed dried milk, pulses, and fish. Infants were allowed 2 to 3 tins of condensed milk a week. Rickets and famine oedema were common, although plentiful supplies of tomatoes and oranges prevented any danger from scurvy. In Barcelona dried whole milk and cod-liver oil were distributed. In schools dietary treatment was combined with rest and exposure to sunlight, the degree of activity allowed being graded according to the child's fitness. When possible relief should be given to families rather than to colonies of separated individuals, who were often sick persons more suitable for hospital treatment. Care should be exercised in the use of unfamiliar foods. Thus undigested bean caused a severe outbreak of gastro-enteritis. Army foodstuffs were usually more suitable.

Prof. E. NOBEL recalled the feeding of Austria and other prostrated countries in 1919. The provision of meals for children was under the direction of Dr. von Pirquet and extended over three years. A charge of 5d. per child per meal was made, which met the cost of foodstuffs and cooking. The degree of undernourishment was assessed by the ratio of body weight to sitting height, and convenient code words were devised whereby the nutritional state of the children could be expressed. The need for foods familiar to the people was emphasized also by Dr. DAGMAR WILSON, with special reference to the current situation in Bengal, where a rice-eating population had no facilities for cooking the wheat imported to relieve the famine.

Discussing opportunities for nutritional research in the work of relief Miss E. M. M. HOME of the Lister Institute said such opportunities would undoubtedly exist after the present war, but for much shorter time than after the last, because modern knowledge should permit the rapid cure of acute forms of deficiency. Research workers acting in liaison with relief organizations and with full official backing might gather useful information on the incidence of subclinical deficiencies. Data might be obtained of minimum amounts of the various nutrients necessary for health; these would give guidance to the relief organization as to the real need for the very high levels that had been recommended in some quarters. Dr. A. P. MEKLEJOHN predicted that the conditions for nutritional research would be very different from those prevailing after the last war, and suggested the organization of strong reconnaissance groups to examine families at random in regard to dietary history, blood haemoglobin, vitamins C and A in the blood, and vitamin A by the dark-adaptation method.

The opening meeting of the 1943-4 session of the Ulster Medical Society was held on Oct. 21. The outgoing president, Dr. ROBERT MARSHALL, introduced Dr. W. DICKEY to the chair. Dr. DICKEY delivered his address, "A Problem of Race." After quoting the statement that Irish nurses are more susceptible to tuberculosis than those of the rest of Great Britain, he traced the various races of Europe from very early days, and then discussed the theories of heredity. He concluded a very interesting address by saying that there is no evidence of any racial susceptibility to disease.

The number of cases and suspected cases of leprosy in Germany was 24 at the end of 1942 (*Reichsgesundheitsblatt*, 1943, 18, 393). Of these, 12 men and 6 women were under medical treatment; 14 cases in Prussia, 7 in Hamburg, 2 in Württemberg, and 1 in Ostmark. Two new cases occurred in the year: one of these was formerly a sailor and the other was a Ukrainian. Three lepers died during the year.

Correspondence

Epidemic Infective Hepatitis

SIR,—I read your leader on epidemic infective hepatitis (Nov. 27, p. 680) with great interest, as I have been an impotent observer of this condition for almost six years. Dr. Edwards tells me that he saw a case in this sanatorium as early as 1925 and that cases have been occurring since then. Although the main features agree with observations on other outbreaks there have been minor variations.

1. For over four years the disease was restricted to one of our ward blocks, although ambulant patients from all four blocks shared the same dining-hall and entertainments. On a few occasions infection has passed between inmates of a two-bed cubicle. Since 1942 cases have been appearing on one other block. The crops have rarely exceeded two cases. The disease, therefore, does not appear here in epidemic form, and I suggest that this low infectivity in the open-air conditions of sanatorium life supports the theory that the infection is air-borne.

2. Only one member of the staff has been infected (cf. Evans, 1942).

3. As the period of infectivity has not been determined the incubation period is doubtful in cases of continued contact. But as our cases have cropped up fairly regularly at approximately monthly intervals with occasional gaps of two months it has been assumed that they were due to serial case-to-case infection with an incubation period of approximately one month, and that missed cases bridged the gaps as suggested by Newman (1942).

4. In about half of a series of cases the erythrocyte sedimentation rate was markedly slowed when the jaundice was at its worst. At the following monthly estimation the rate had returned to approximately the pre-jaundice level. Any change for the better or worse could be attributed to the tuberculous process (cf. Evans, 1942).

5. There has not been a death in my own series, but a death from acute yellow atrophy in 1933 may have followed infective hepatitis. Only one case in my time has caused serious concern. Pleural effusion developed in the pneumothorax of two cases, but this was probably chance.

6. In the average case the onset has been sudden with slight fever, malaise, headache, and possibly vomiting. Conjunctival icterus appeared within 48 hours.

7. No case of jaundice has been reported among the sanatorium pigs.

I feel that a useful field for epidemiological research has been rather wasted on us because the liver happens to be situated below the diaphragm.—I am, etc.,

Sheshire Joint Sanatorium, Market Drayton. A. CLARK PENMAN.

gnosis of Endogenous (Spontaneous) Hypoglycaemia

SIR,—The diagnosis of spontaneous hypoglycaemia seems to be becoming too popular, and an increasing number of cases are referred to me to decide whether a pancreatic operation or merely diet regulation is necessary. Most have had suggestive symptoms of weakness, dizziness, or even minor "black-outs" some hours after meals, apparently relieved by carbohydrate food, and most patients bring me glucose-tolerance tests after glucose supposed to prove hypoglycaemia. The majority of these curves have been completely normal, and there seems to be a widespread misconception of the range of normal blood sugar (b.s.) on which a few facts may be useful. The fasting b.s. normally ranges between 70 and 100 mg. per 100 c.cm. blood. Most lie between 80 and 95 mg., but figures between 70 and 80 mg. are not uncommon, and unless the level is below 70 mg. per 100 c.cm., either fasting or after glucose, pathological hypoglycaemia is disproved. Indeed, symptoms are not likely to be produced unless the b.s. is 60 mg. per 100 c.cm. or below. Another misconception is to look upon a flat curve that hardly rises from the base line (e.g., 80, 95, 85, 75, 78 mg. half-hourly after glucose) as indicating

hypoglycaemia, though this is not infrequent in healthy students, and merely shows a high "C tolerance" and a well-balanced b.s. regulation. It should be unnecessary to point out that such diagnostic investigations must be carried out with great accuracy and in duplicate; but I get a lot of curious curves which won't repeat.

The ordinary glucose tolerance carried out for 2 or 2½ hours is not a conclusive procedure. The real proof of hyperinsulinism from pancreatic tumours is the progressive fall of the b.s. on fasting. But a b.s. curve carried on for 4 to 6 hours after glucose is, in my experience, a useful test to show the type of spontaneous hypoglycaemia in which the b.s. swings down below 70 mg. per 100 c.cm. blood, sometimes accompanied by symptoms, for a brief period and then recovers spontaneously—e.g., 85 (fasting), 120 (1½ hour), 110 (1 hour), 70 (1½ hours), 60 (2 hours), 70 (3 hours), 85 (4 hours), 85 mg. per 100 c.cm. (5 hours). Such patients require no treatment other than a small carbohydrate meal halfway between the main meals of the day.

I think true endogenous hypoglycaemia of any type is very rare, and overdone at present as an explanation for minor indispositions.—I am, etc.,

London, W.1.

R. D. LAWRENCE.

Industrial Lead Poisoning

SIR,—Industrial health is receiving increasing attention in the medical press. This is a step those of us interested in this branch of medicine very much appreciate. It is important, however, that articles on industrial subjects should be accurate and should not mislead newcomers to this field. These comments are prompted by a recent leading article on industrial plumbism in the *Journal* of Oct. 23 (p. 515). In the first paragraph there are misstatements of figures of case incidence. The peak incidence of lead poisoning cases in 1924 was due to the high incidence both in ship-breaking (131) and in electric accumulator manufacture (101), while the number of cases in 1934 was certainly not due, as stated, to the manufacture of electric accumulators, since in this year the number of cases in this industry had fallen to 12.

This may be passed over as a matter of detail. A much more important fault, however, is that the article fails to differentiate clearly between the diagnosis of lead poisoning and the control of an industrial lead hazard. The former depends upon the clinical picture, aided, perhaps, by certain scientific findings; the latter can be achieved only by scientific aids and by a proper appraisal of clinical findings where these exist. The appearance of symptoms and the production of a clinical picture are evidence of the failure of control. The article quotes recent American work, and accepts uncritically conclusions concerning the place of punctate basophil counts in the control of a lead hazard. These conclusions are based on a very small number of cases. The work, moreover, contains an obvious fallacy. That such an article should receive this added publicity is unfortunate, since your article may throw into disrepute a measure for the control of an industrial lead hazard which has been proved reliable beyond any shadow of doubt.

The great improvement brought about in the largest section of the electric accumulator industry over the last 15 years has been made possible by the use of the following scientific aids: (1) lead-in-air determinations; (2) punctate basophil counts, together with haemoglobin estimations; (3) lead-in-urine determinations. Probably the most useful of these, from a practical point of view, has been the blood examination, not to show the particularly susceptible individual (though this is useful) but to indicate varying degrees of exposure among groups of workers. It would be a great pity if the proper use of this method for the control of a lead hazard were questioned on such evidence as is used in the leading article in question.

A final mistake might also be pointed out. The article states that the blue line indicates severe exposure. This is not so. The presence of a blue line depends as much upon the individual exposed as upon the severity of the exposure. The frequency of blue lines in a group is helpful evidence in estimating and controlling a lead hazard, just as punctate basophil counts or lead-in-urine determinations; but the finding

of a blue line in an individual case has but little significance in itself beyond indicating that lead is being absorbed, and it certainly gives but little idea of the degree of severity of exposure to which the individual has been subjected.—I am, etc.,

Manchester.

RONALD E. LANE.

Malignant Tertian Malaria

SIR,—May I be allowed to register a plea for what I will call the "twentieth case"?

Those of us to whom English mails are a fortnightly, rather than a daily, occurrence tend to read our *Journal* with an assiduity perhaps not always accorded it at home, and on many subjects which do not directly concern us—such as Beveridge plans—we find the contrariness of opinion most stimulating. It inevitably happens, however, that your printed matter touches at times on tropical diseases, which do concern us more nearly. This has been increasingly so of late, since war conditions have enabled a comparatively large number of men—doctors among them—to spend a short while on the West Coast of Africa and acquire that little knowledge which is so dangerous a thing.

It is becoming increasingly apparent, therefore, that cases of malaria in England are being treated by the general practitioner and in general hospitals. Nineteen times out of twenty the patient will recover dramatically, whatever the treatment, and some such cases get reported in your pages. But there is the twentieth case—the one which not so very long ago was principally responsible for the term "the white man's grave"—and this case treated in inexperienced hands is going to prove fatal with a monotonous regularity. It is further unfortunate that not even the most experienced can tell at the onset whether the case seen is going to prove one of those twentieth cases.

My plea, therefore, is that every single case of malaria—and owing to our geographical proximity the majority are infections contracted on the West Coast—should be treated by doctors with considerable tropical experience, preferably in the existing tropical hospitals, but if expense forbids I am sure the Colonial Office, if approached, would be only too pleased to lend the services of some medical officer, preferably from the Colony where the disease originated, who may be home on leave in the area.—I am, etc.,

Accra, Gold Coast.

J. S. MINETT.

Therapeutic Fallacies

SIR,—While in agreement with most of the well-balanced statements by J. W. Linnell and W. A. R. Thomson (Nov. 6, p. 572) I hope that the following critical remarks may be found helpful.

It may be true that there is no evidence that nervous strain can produce hypertension, but there is much clinical evidence that such strain tends to hasten the fatal outcome in an established case. Fatalities due to sudden nervous strain do occur even in the large group of undiagnosed and symptomless hypertension. I would therefore hesitate to take the responsibility of keeping all patients in ignorance of their condition, as the authors recommend.

There is no scientific evidence that hypotension conveys anything like "almost certain immunity" to hypertension. Like others I have seen several cases to the contrary.

The prognosis of paroxysmal tachycardia rests on the underlying condition and not on the location of the ectopic pace-maker. While it is true that ventricular paroxysmal tachycardia is more often seen than supraventricular with coronary heart disease, simple ventricular tachycardia in otherwise healthy subjects is no more dangerous than other forms of ectopic tachycardias. The boggy of ventricular fibrillation in these cases is a textbook one only. It is true that digitalis only exceptionally stops attacks of tachycardia, but I remember vividly a child of 8 almost unconscious with a tachycardia of 308 per minute, in whom a single dose of digitalis intravenously proved life-saving. The action in such cases is by atrio-ventricular block. Full doses of digitalis prove most effective in preventing attacks of auricular fibrillation in certain cases where these attacks are probably due to otherwise latent heart failure. I cannot agree to the unqualified recommendation of quinidine at frequent intervals in congestive heart failure

due to attacks of paroxysmal tachycardia. This drug has a dangerous depressing action on the myocardium, and should only rarely (and then in expert hands) be given before cardiac failure has been checked by digitalis.

Though the use of arsenic in pernicious anaemia is now obsolete, it is incorrect to deny its action in megalocytic anaemia, which has been proved in countless cases before the advent of liver—e.g., in the form of single massive doses.

The authors state the ineffectiveness of the usual expectorants. But do they really believe that steam inhalations, which they recommend, are more than a placebo, as these never reach further than the fauces? There are, however, more active expectorant principles, such as rad. primulae and others though they are less popular. The indiscriminate prescription of digitalis in pneumonia is rightly condemned, but the argument "a poison in an already poisoned heart" is too simple to be true. What about digitalis in the failing heart of toxic goitre?

Finally, a word of warning against the regular use of enemata in chronic constipation. This is widely practised on the Continent, and the effects are hardly less harmful than those of regularly taken aperients. The conditioned defaecation reflex is almost irreparably blunted, and the psychological effects are equally bad. Contrary to the authors' optimistic advice of "constantly decreasing daily enemata," the amounts of fluid used have to be increased as time goes on. Chronic constipation is a most difficult condition to cure, and careful adjustment of the habits of life and individualized though elementary psychotherapy are the essentials of treatment. Prohibition of advertisements for liver-salts and similar laxatives would be a useful prophylactic measure.—I am, etc.,

Stratford-on-Avon.

MAX WINTERNITZ, M.D. Prague.

Sulphathiazole in Impetigo

SIR,—Dr. H. MacCormac's reference to this treatment (Nov. 27 p. 667) is timely, and bears out my own experience in dealing with impetigo in the war factories under my medical charge. During the past two and a half years the infection has a times assumed almost epidemic form. Routine treatment with ammoniated mercury and zinc paste, copper and zinc lotion and ferri perchlor. fortis, all gave fair results, but failed to prevent absence from work in many cases. Sterilized sulph. anilamide powder was then tried with some success, but toxic side eruptions were not uncommon. Four months ago I started using 5% sulphathiazole in 15% zinc and starch paste, as recommended in the M.R.C. War Memorandum, No. 10. The results have surpassed those obtained by any other form of treatment, impetigo clearing up in a few days without loss of working time. The use of the paste has been extended to furunculosis and acne, both of which are common in these war-diet days, and with equally gratifying results. I have not seen a single case of intolerance to sulphathiazole even after it has been rubbed into the skin of acne patients nightly for many weeks; indeed its use in this way eliminates all pimple and blackheads and tones up the skin in a remarkable manner. Strangely enough its continued use on the chin and naso-labial area seems to inhibit the growth of staphylococci also in other areas of the face and neck remote from the site of the inoculation.—I am, etc.,

N. HOWARD MUMMERY,
Aircraft Factory M.O.

Scabies and Impetigo

SIR,—Dermatologists are indeed fortunate, for not only do they enjoy undisturbed nights but their specialty does not seem to involve any tedious considerations of the social background of disease.

I have previously pointed out that scabies is a disease with a social threshold. Those people who sleep in single beds and remove their vests when they put on their pyjamas seldom, if ever get it. The social threshold is less obvious with impetigo, but it undoubtedly exists. One reason, of course is careless tolerance of unsightly blemishes; but another is communal use of towels and washing apparatus. A professional household would provide a bath and face towel for everyone which, allowing for laundry, means at least four towels per head. Actually a household of ten would not consider six

at all excessive. A working-class family of ten might have a dozen towels; I have known as few as four.

When, therefore, we encounter a disease so infectious that its very name means "a rushing on," the first thing to do is to order separate towels. This may sound faddy to some people, but if, instead of thinking in terms of ointments and tablets, we apply our surgical knowledge of infection, the necessity is obvious.—I am, etc.,

Norwich.

FREWEN MOOR.

Stilboestrol in Breast Cancer

SIR.—The account given by Dr. R. Tudor Edwards (Nov. 20, p. 659) of his case of breast cancer treated by stilboestrol is interesting, as the observations on his patient were so carefully carried out. They should encourage those who are interested in the treatment of cancer. Control of this disease cannot come through the use of the knife, by radium, or, I fear, by x-ray therapy. Some substance must be looked for which will cause the destruction of the carcinomatous cell throughout the body, in the primary growth, the infected glands, and the floating cells which are already in the blood stream or have settled in the internal organs.

A word of caution, however, seems needed. No year date is given for the case, so presumably the whole phenomenon took place from January to October of this year. This can hardly be accounted as cure, and a much longer period must elapse before such a claim can be made. No such claim is made by the author, but careless readers might possibly assume it. There are so many instances in the literature which have been "cured" for long periods. It is significant, however, that all such cases have either recurred or been lost sight of (which most commonly happens), or the patients have died of intercurrent disease at no distant date. I am unaware of any cure which has been permanent. Many have received no treatment at all, others have been treated in many and various ways by medical practitioners, and naturally to the treatment they were undergoing the cure is attributed. In some cases quacks have treated genuine cases handed over to them by surgeons, and the "cure" has lasted for upwards of 22 years. These facts are mentioned not to detract from the excellent result referred to, but to urge Dr. Tudor Edwards to keep in touch with his patient and to publish the result, say, at 5-yearly intervals.

I have treated many cases of breast cancer with stilboestrol during recent years, but have not been fortunate enough to meet with any such encouraging result.—I am, etc.,

Light Ether Anaesthesia

SIR.—Dr. R. Blair Gould (Nov. 13, p. 607) gives a timely warning against anaesthetists trying to do too much with nitrous oxide anaesthesia, but he does not quite give the answer to the question as to what technique should replace this unsafe proceeding.

After using the Oxford vaporizer on a series of 500 cases I am beginning to appreciate the real value of this machine in producing the lighter planes of ether anaesthesia. There is a very gradual increase in the strength of ether vapour given by this apparatus that one can give an anaesthetic of no more toxicity than nitrous oxide-oxygen, keeping a bright pink patient unconscious with the lid reflex only just abolished. I use a mixture of trilene 20%, ether 80%. If a quick induction is desired this can be carried through with ethyl chloride until consciousness is lost and then on to trilene-ether with the indicator of the vaporizer at "10" or less. (The limitation of the amount of ethyl chloride is important.)

This technique is excellent for old, ill patients—as, for example, the emergency suprapubic drainage—and in such cases I find the patients talk to us before they leave the theatre. Recently I had a case of extra-uterine pregnancy in a woman with profound heart failure. The operation was difficult and took time, but so light an anaesthesia was maintained that she was actually moving her head before the bandages were fixed, and appeared little worse than before operation.

I am satisfied that light ether anaesthesia is far less harmful than attempts to perform an abdominal operation with nitrous

oxide-oxygen only, but it must be really light ether. No old machine I have ever used will give this anaesthesia except the Oxford vaporizer, because no other machine gives such a very gradual increase in ether vapour, which is essential for comfort of the patient and for avoiding coughing and straining.

If the patient is too lightly under, as may be shown by movements of limbs, by merely moving the indicator slowly one can deepen the anaesthetic without the resistance which would result from pouring more ether on to an open mouth. There were such light planes of anaesthesia attempted with the old technique. For the general practitioner the vaporizer appears to me to be the apparatus of choice for anaesthetizing the bad-risk patient. I cannot help noticing with regret how few newly qualified men and women have ever seen a vaporizer. For the full-time professional anaesthetist there is a wide choice of techniques for the bad-risk operation, but the occasional anaesthetist either is, and is likely to remain, the safest anaesthetist. I have certainly not noticed any marked tendency to chest complications after properly administered ether than after local anaesthesia.—I am, etc.,

New Barnet.

JOHN ELAM

Adjuvants to Nitrous Oxide Anaesthesia

SIR.—I have read with great interest Dr. R. Blair Gould's article on nitrous oxide anaesthesia (Nov. 13, p. 607). I am in complete agreement with him on the supreme necessity of avoiding anoxia in this or any other type of anaesthesia. I agree that where nitrous oxide-oxygen is used alone it is usually difficult to avoid anoxia, except in the case of short operations not requiring relaxation. I think, however, that it is feasible to avoid this consequence of nitrous oxide-oxygen anaesthesia by supplementation with other agents. For that purpose the commonest adjuvants are as follows:

1. Ether, trichlorethylene, chloroform. Of these ether takes pride of place, particularly in inexperienced hands. In many cases, however, the anaesthesia is purely due to the ether, nitrous oxide-oxygen simply serving as a vehicle for conveying the ether vapour. The latter is irritant, toxic, explosive and liable to give rise to unpleasant sequelae. It should therefore, where possible, be avoided. Trichlorethylene is only slightly toxic, non-irritant, and non-explosive, but it does not give adequate relaxation where this is required. In order to avoid tachypnoea and cardiac irregularities a high percentage of oxygen is necessary, so that, again, the anaesthesia is nitrous oxide-oxygen supplemented by trichlorethylene, rather than is mainly accomplished by the trichlorethylene. Chloroform has all the disadvantages of ether (except irritability and explosibility) in addition to certain grievous effects peculiar to itself, such as its toxic action on the cardiac muscle or the ever-present possibility of sudden death in the early stages of anaesthesia. The indications, therefore, for chloroform as an adjuvant to nitrous oxide are practically non-existent.

2. Cyclopropane. This is an exceedingly efficient supplement to nitrous oxide-oxygen, particularly where relaxation is required. The disadvantages are expense (or the necessity for a closed circuit apparatus with carbon dioxide absorption) and explosibility.

3. Spinal anaesthesia. For the longer abdominal operations on comparatively fit subjects a "high spinal," whereby suprapubic relaxation of the abdominal muscles is combined with quiescence of the viscera, is ideal, the patient being kept unconscious by means of a light nitrous oxide-oxygen anaesthesia. Nevertheless, the well-established contraindications to spinal anaesthesia, if abused, trouble will result and an otherwise useful technique will fall into disrepute.

4. Continuous pentothal sodium anaesthesia. This forms an excellent supplement to nitrous oxide-oxygen, though again there are definite and well-defined contraindications to be observed, as well as certain cases in which particular care is necessary. The simplest method of administration is a 5% solution contained in a 20-c.cm. syringe strapped to the arm, the needle being retained in the vein throughout and the solution injected as required. Continuous pentothal sodium-nitrous oxide-oxygen forms a pleasant combination from which there is absence or diminution of those after-effects which, while not dangerous, are so trying to the patient in the post-operative period.

5. Local anaesthesia. This is the method *par excellence* in all cases which may be classed as poor surgical risks. For abdominal work, as in the case of a "high spinal," relaxation is obtained by means of injection of the anaesthetic agent while the patient is kept unconscious by nitrous oxide-oxygen anaesthesia given with abundant oxygen. Many techniques are available and are described in the literature on the subject. Contraindications are injections through septic areas or scar tissue; these may be overcome by avoiding local infiltration and hitting off the nerves at a distance, as in intercostal nerve block. The disadvantage is that the injections are time-consuming compared with any of the other means of obtaining anaesthesia; but this, one feels, is a matter of small importance, at any rate when dealing with the very sick, feeble, or aged subject.

The above, then, are the chief methods of obviating the anoxia inherent in pure nitrous oxide-oxygen anaesthesia. It is only by consideration and evaluation, one against the other, of the four factors present at any operation—i.e., the condition of the patient, the experience and capabilities of the anaesthetist, the type of operation, and the likes and dislikes of the surgeon—that one can assess and judge which of these methods is best in a particular case.—I am, etc.,

London, N.W.3.

HELEN BOWER ALCOCK.

Anaesthetist's Third Hand

SIR.—The appearance of a description of an "anaesthetist's third hand" has for me a semi-historical interest. I had occasion to design a similar device some years ago. The idea occurred to me during a discussion with some aeronautical experts on the possibilities of development in aviation afforded by the new plastic processes, and in particular that of bonding rubber to metal. A rubber-to-metal bond was incorporated in the device, which was of the following construction.

Support for the chin was provided by an oval concavo-convex rubber pad mounted on an oval stainless steel hoop. The patient wore a rubber skull cap similar to those commonly used during a tonsillectomy. To the vault of this cap was attached a rectangular metal plate. The attachment was by the rubber-metal bond referred to above. The metal plate was placed in an antero-posterior position and slightly curved on the flat, in order to fit fairly closely to the head.

Mounted at the posterior end of the plate was a slightly curved corrugated spring. The composition of the steel used for this spring required careful selection in order to obtain the necessary degree of resilience and flexibility without producing early fatigue in the metal. In use, the chin pad having been adjusted, the direction of pull was obtained by choosing a suitable notch in the corrugations of the spring. The strength of pull was varied by the small adjuster screw at the base of the spring.

Although I designed this instrument while a resident anaesthetist giving some twenty anaesthetics every day, and using an endotracheal tube several times daily, the device was primarily intended for use with an "open method." Consequently, the following refinement was added. To one lateral curve of the steel hoop, a hollow tube was welded. Anteriorly the tube curved over, to approximate the end of the tube to the corner of the mouth. The other end of this tube was connected to an oxygen supply, usually a small cylinder of oxygen clamped under the head of the operating table. A tap in this tube enabled one to turn on oxygen without even looking away from the patient at what might be a critical moment. Not unnaturally, to my confusion and dismay, the device was thereafter referred to as "Jackson's gas ring!"

It is my impression that, apart from other aspects, there are three fundamentals required in every anaesthetic. The first is the establishment of confidence and assurance in the patient. This requires that the anaesthetist should see his patient before—preferably the day before—the "anaesthetic occasion"; the second is the establishment of anaesthesia, usually the only consideration. The third consideration is the establishment of an airway—which will require no further interference. Although I am opposed to multiplication of apparatus and complications in anaesthetics, I feel that there is scope for a "third hand" which will provide constant and even support for

the jaw; in fact I feel that some device which is artificially steady is needed to maintain the establishment of a good airway. Furthermore I consider that a support for the jaw is an advantage if it avoids the trauma of an endotracheal tube.

I should add that I do not advocate the use of any form of "third-hand" apparatus either of the "Heyworth hook" or "gas-ring" variety except under conditions in which inexperienced interference will not be encountered.

—I am, etc.,

Monkseaton.

J. NOEL-JACKSON, M.B., B.S.

Congenital Jaundice in a Man aged 77

SIR.—From the short data given in my letter printed on Nov. 27 it appears that the present case is one of congenital idiopathic hyperbilirubinaemia—the bilirubin in the blood being, of course, "blood bilirubin," which is probably the same as what Virchow called haematoidin—differing, however, from the hyperbilirubinaemia of the well-known cases of familial haemolytic (acholuric) jaundice, notably by the absence of excess of urobilin or urobilinogen in the urine. I suggest that the blood bilirubin in this case is in some way "dammed back" in the circulating blood, as if the threshold for its elimination or catabolism were high. The mere excess of blood bilirubin in the blood, of course, does no harm, though it makes the blood plasma too yellow and produces the jaundice and causes a highly positive indirect van den Bergh reaction. Is it possible that this hyperbilirubinaemia in our present case is the sole obvious result of a new gene mutation of germ cells, which has not (yet) manifested itself in the children and grandchildren because it is not a Mendelian dominant like ordinary familial haemolytic (acholuric) jaundice is?—I am, etc.,

F. PARKES WEBER.

Arsenicals in Vincent's Infection

SIR.—As a dental surgeon I am disturbed to see in Major John Davis's letter (Oct. 9, p. 464) mention of "the pain and discomfort attendant upon a large number of local treatments" for Vincent's infection. One cannot help wondering what can have been the nature of this so painful local treatment. All who have given local treatment to a large number of cases know well the immediate relief afforded the patient by the simple application of chromic acid and hydrogen peroxide as described in Squad. Ldr. Jewesbury's article (Sept. 18, p. 360), or, in the worst cases, by careful swabbing of the ulcerated areas with pure carbolic acid. The patients invariably express gratitude, for the disappearance of the pain is quite spectacular. Scaling is only begun when the gingivae are no longer painful. On the other hand, it is not my experience that intravenous N.A.B. alone produces any such beneficial effect.

So dogmatic a statement concerning "pain and discomfort" from local treatment is not only misleading but decidedly harmful, for if taken at its face value might do much to discourage resort to oral hygiene, the value of which has been so abundantly proved.—I am, etc.,

SELWYN HOLMS,
Flight Lieut., R.A.F.V.R.

Misuse of Vasoconstrictors in Coryza

SIR.—Is it not time the general public was given a word of warning on the use of ephedrine preparations and volatile vasoconstrictors in acute rhinitis? In general practice during the last few years, and latterly since joining the R.A.F. Medical Service, I have seen an increasing number of patients suffering from sinusitis, Eustachian and post-nasal catarrh following the common cold; in these cases I frequently get a history of relief being sought by the use of some form of vasoconstrictor. Further, from my own personal experience I believe that on more than one occasion I have caused a lower nasal infection to spread by shrinking up my nasal mucosa before any active immunity to the infection has been achieved.

It seems reasonable to suppose that Nature, by the swelling of the turbinates in the early stages of infection, cuts off the intricate upper nasal passages from the lower; shrinking of the turbinates with vasoconstrictors opens up the sinuses and ethmoidal cells; after this, blowing of the nose forces infected material into the upper air spaces, and so causes sinusitis, ethmoiditis, and even middle-ear troubles. By counteracting the natural method of germ destruction—i.e., inflammation—one

Illustrating the jaw support

surely prolongs the infective state, and for the sake of a few minutes' comfort and relief from the oppression caused by nasal obstruction one risks serious complications.—I am, etc.,

T. M. DAVIE,
FJO, R.A.F.V.R.

Treatment of Symptomless Pulmonary Tuberculosis

SIR,—Dr. E. Weatherhead's helpful letter (Nov. 13, p. 621) regarding the treatment of symptomless pulmonary tuberculosis in adolescents, as outlined in the report of the work of the Brompton Hospital Research Department, has served to show that there are some points in the report which require a fuller explanation.

The report evidently gives the impression that after a patient has been found to have radiological evidence of pulmonary tuberculosis artificial pneumothorax treatment is "resorted to forthwith." This is far from the actual procedure. In the first place, by keeping the patient under clinical and radiological observation, great care is taken to make sure that the diagnosis is a correct one. After this has been established, further careful observation is carried on over a period of weeks or months before collapse is decided upon. We have found, however, that there is a danger here; sudden unpredictable exacerbation of the disease may take place, in which event collapse therapy becomes a palliative and not a curative treatment.

With regard to shallow artificial pneumothorax as against complete collapse of the lung, it is quite realized that a shallow pneumothorax gives only a partial relaxation or splinting of the lung, but it appears from our experience that this is all that is necessary to enable early lesions to heal. It also has the advantage, again in our experience, that it is less likely to be followed by complications.

The phrase "as yet it is impossible to assess its value" should read, "as yet it is impossible to assess its full value."

Although the work of the Research Department has been going on for a period of 14 years, that period is not long enough for us to have followed a sufficient number of these cases to provide the data necessary to give conclusive statistical information about the behaviour of these cases. Our results are admittedly incomplete, but we considered it would be helpful at this time to put forward our suggestions for treatment by a shallow pneumothorax as a "reasonable alternative" to other methods, which, from our observations, have not given satisfactory results.—I am, etc.,

Brompton Hospital, S.W.3. A. MARGARET C. MACPHERSON.

Treatment of Septic Hands and Fingers

SIR,—I read with interest the letter from Mr. Charles Romer (Oct. 30, p. 556). While it is impossible to discuss, without specific figures, the matter of "over-ripe" septic fingers that arrive at hospital, I feel that a few comments from another recent junior house-surgeon would not be amiss.

(1) I was one of two working in a casualty department in a London hospital. The total number of patients seen was out 1,200 per week, and I am happy to say that I saw only one "over-ripe" finger. I did, however, see a large number the stage of invasion, and I am surprised that Mr. Romer's only 5% at this stage. Could this be due to premature incision? I had no cases of necrosis of the terminal phalanx.

A G.P. usually sends a patient to hospital for incision an infected finger, and so long as this is done efficiently he is quite willing and competent to supervise the after-care of the finger—a service for which he is paid in the case of all N.H.I. patients. If only the house-surgeons would realize this fact they would reduce the numbers of patients attending their out-patient departments, thus saving much of the patients' time and giving themselves more time to deal with the cases that need hospital treatment. Furthermore, the hospital funds would not be wasted by treating cases that an equally competent doctor is already paid to treat. (3) I venture to point out that Mr. Romer is running true to form as a newly qualified junior house-surgeon by inferring that the majority of G.P.s are nincompoops whose clinical judgment is valueless.

Again I wish to emphasize that I am a newly qualified house-surgeon and not a general practitioner.—I am, etc.,

A. G. S. BAILEY.

Bourne End, Bucks.

Psychiatry at the Cross-roads

SIR,—I am appalled to read the letter of Dr. J. Stephen Horsley under this heading (Nov. 13, p. 620). He states that medical superintendents appoint as medical officers not colleagues but "yes men." I am now working in my fourth mental hospital (fifth if a neurosis hospital is included) and I have not yet found this glib assertion to hold a particle of truth. I have experienced only kindness, interest, and eagerness to assist in any treatment the medical officers have thought of value in the interest of their patients. I have never seen any need to consider the interests of my chiefs, who I am sure would soon have dispensed with my services had I done so to the detriment of my clinical work. They have expected hard and good work from their assistant medical officers, and when it has resulted in an unexpected improvement they have never grudged a "Well done." I have never seen a keen and efficient medical officer snubbed, and as for rivalry between superintendent and his assistant medical officers I am at a loss to understand this statement.

It may be that Dr. Horsley has been unlucky in the superintendents he has met, or that he is exhibiting a mental mechanism, or that I have been exceptionally lucky. I should have thought, however, that four gave a pretty accurate cross-section of medical superintendents as a class. Anyhow, I am proud to look back on my ex-superintendents as my teachers, co-operative colleagues, and my present friends.—I am, etc.,

Wallingford.

R. E. M. COKE HARVEY.

Medico-Legal

CONDITIONS IN DETENTION BARRACKS

Public misgivings about cruelty or unnecessary hardship in military prisons and detention quarters will be allayed, if not wholly set at rest, by the report of the Prime Minister's Committee of Inquiry presided over by Mr. Justice Oliver.¹ The misgivings had their origin in the trial at Maidstone in the earlier part of this year of two non-commissioned officers for the manslaughter of a private under detention, ending in their conviction and sentence to 18 and 12 months' imprisonment. The committee of inquiry (whose medical member was Dr. H. E. A. Boldero, Dean of the Middlesex Hospital, in place of Lord Moran, who was originally appointed and found himself unable to serve) has carried through its work with commendable speed, visiting thirteen military prisons, detention barracks, and naval detention quarters in the course of five weeks, and holding more than two hundred individual interviews with detained men. The committee is satisfied that there is not at present, nor has there been for some time past, any calculated brutality or so-called "Gestapo methods" in these establishments, as has been alleged by sections of the Press, though it is less assured as to conditions prevailing in the early part of the war; and it is quite clear that in matters of staffing and in some details of hygiene and sanitation the conditions at present obtaining ought to be improved.

Inherent Difficulties

The difficulties attaching to what is in effect a prison system for men in the fighting Services—though detention does not carry quite the stigma of imprisonment—must be appreciated. Civil prisons no doubt stand in need of reform, but they have a selected, trained, and disciplined staff of warders. The men corresponding to these in the Army prison service are N.C.O.s who have received little or no training for such work, and are unlikely in many cases to have the patience, skill, tact, and firmness which the work demands. Moreover, most of the men under detention are not of the kind customarily found in civil prisons. The majority are men who, while they do not get into trouble with the authorities in civil life, are unequal to the additional liabilities and submissions which a member of the fighting Forces must undertake. Many of them are difficult people—men with grouses, trouble-makers, and determined on antisocial conduct—but there are others whose transgression is

¹ Report of the Prime Minister's Committee of Inquiry into Detention Barracks, 1943. Cmd. 6484. H.M. Stationery Office. (6d.)

due to family trouble or other pressure and who during a period of detention ought to be educated and encouraged. Among them also are men of another type, conscientious objectors, many of whom are of the highest character and of exceptional intelligence, but their considered, though perhaps polite, refusal to submit to orders may be more infuriating to a certain type of subordinate officer than the insolence or occasional violence of others. It is noteworthy that the only two witnesses with whose demeanour the committee says that it was "very favourably impressed" were conscientious objectors. Both told stories of violence which they had witnessed, and which presumably the committee believed, but the stories related to 1940, and to a state of affairs which, it is hoped, has since passed away.

Medical Care

The medical officers concerned seemed to the committee to be well suited to their work, but some of the quarters are served only by part-time officers, and there was some apprehension as to whether they might be quickly available in emergency, though no instance of non-availability was reported. The committee thinks it desirable that a whole-time medical officer should be appointed to each detention barracks, that he should be changed not too frequently—though it is obvious that this is not the kind of work to which a young man should be consigned year after year—and that he should have an aptitude for this rather specialized and difficult employment. If aptitude for the work means an interest in it we imagine that such men may not be easy to find, for it is difficult to imagine a less engaging environment. The medical officer is the natural target for complaint by the men who plead some disability as the easiest way of being excused the harder parts of their routine and find him not so ready to give credence to them as they had expected. At present the time a man spends sick or in hospital counts as part of his sentence. The committee thinks that the task of medical officer would be easier if it did not. The short accounts of ninety or more of the interviews which the committee had with men who complained of grievances make a melancholy recital, sometimes of malingering, but more often of exaggeration of physical defects and infirmities. Many of the assertions of the men were capable of immediate disproof, and when the medical officer was implicated in the complaint and the facts could be tested the committee in every case, after inquiry, upheld his decision. Some of the men showed ingenuity in describing their ailments, and a familiarity with medical terms. Thus one of them complained of "urethritis," though the committee found there was no substance in the complaint. Another said that he had had "arthritis foot"; it was found that he had had gonococcal arthritis, but there was no evidence of disability remaining. Another said that he had "asked to be psychiatrized and had been refused," but it was ascertained that he had already been sent to a psychiatrist.

Sick Quarters, Sanitation, and Food

On two points the committee makes important recommendations. In every such place there should be a room or rooms which can be used for cases of minor sickness. It is undesirable that such cases should be cared for in the usual sleeping quarters, and the use of a neighbouring hospital is not an ideal solution. Another matter on which men made several complaints, and which the committee endorses, concerns the sanitary condition of the sleeping quarters. The men are locked up in their rooms from late afternoon or very early evening until next morning, and the only sanitary arrangements in the rooms consist of buckets, and sometimes only one, sometimes two, closet seats. These are in many cases in the sleeping rooms themselves, without any flushing arrangements, and sometimes not even screened. This is a real hardship, and the committee calls for steps to be taken to provide water-closets outside the rooms and with their own ventilation. Four detention barracks are named where these conditions need immediate attention.

On the question of food the committee makes no recommendations. The food appeared to be of good quality and well cooked, maintaining the men in good health, as evidenced by their appearance and by the fact that the majority gain in weight while under detention. The overriding consideration, as in all prisons, is that "durumc vile" must be made less attractive than the conditions under which the men would otherwise be living, or else the object of the penalty is defeated.

The annual report of the Chief Native Commissioner for Southern Rhodesia for 1942 recommends the provision of landing grounds near native clinics in the Native Reserves, especially in remote areas. This would enable serious cases to be transferred rapidly to main centres for skilled hospital treatment. The doctors, he says, should be provided with air transport. The breaking down of the African's prejudice against the "white man's magic" is shown in demands for medical facilities from even the most primitive tribes. The native population is estimated to have increased by 40,000 during 1942, to 1,298,000.

Obituary

TOM BATES, M.B., B.S., F.R.C.S.

The death of Mr. Tom Bates, senior honorary surgeon to the Worcester Royal Infirmary, occurred on Nov. 21 at his residence, 44, Foregate Street, after a very short illness. He was born in Worcester in 1878, being the elder of the two sons of Mr. Tom Bates of Worcester, and was educated at the Worcester Cathedral King's School. He entered St. Bartholomew's Hospital and obtained the M.R.C.S., L.R.C.P. diplomas in 1904 and the F.R.C.S.Eng. in 1905. He obtained the M.B., B.S.Lond. in 1907. He was house-surgeon to Mr. C. B. Lockwood at Bart's and then joined his father in practice in Worcester. His father was appointed honorary surgeon to the General Infirmary (later Royal) at Worcester in 1879 and held that office until 1909 and the appointment of consulting surgeon until 1916, when he died after coming out of retirement to take on the work of his two sons, who had joined the R.A.M.C. Tom Bates succeeded his father as honorary surgeon at the Worcester Infirmary in 1909 and had held that office ever since. His brother, Mark Bates, F.R.C.S., was honorary surgeon for 14 years and is now honorary consulting surgeon and M.O. Venereal Diseases Department. He also was at Bart's.

Tom Bates not only gave untiring service as a surgeon at the Infirmary but his opinion and surgical skill were very highly valued by the practitioners in Worcester and surrounding districts. He never allowed his private practice to interfere with his regular and punctual attendance at the Infirmary to carry out his duties there. The Infirmary and its welfare were truly the pivot of his life, and he gave unstinting service to the patients and to the general running of the medical and surgical services. He was a very regular attendant at all the important committee meetings and was the Infirmary representative on the Hospitals Contributory Schemes Association and chairman of the Area British Hospitals Association. He was not a great talker at meetings and was somewhat impatient with those who liked to hear their own voices. When he spoke, after listening to others, he summed up the salient points in a few words which were devoid of frills. He was an ardent supporter of proposals to improve the nursing profession and was largely instrumental in pressing the claims at committee meetings. He was responsible for starting prizes at the Infirmary for practical and theoretical work of the nurses. He was the representative of the honorary staff on the Infirmary Committee and did all in his power to present its problems to the meetings with justice and equity. He was a staunch and loyal friend to his colleagues and his patients, and his advice was never sought in vain by any of them. His personal integrity was beyond reproach, and he did a lot of good in a quiet way in helping his less fortunate friends and patients. He was very embarrassed by expressions of gratitude for anything that he had done on behalf of the Infirmary or in other ways. He was most hospitable and always welcomed any new colleagues and invited them to partake of his hospitality, and he was at his best when so entertaining. He was keen on bowls and played a good game of bridge, and was always good company and had a subtle humour. He was a regular attendant at the local meetings of the B.M.A., and had been president of the Worcestershire and Herefordshire Branch. He was a keen advocate of clinical meetings and practically always brought cases of interest before the meeting. He took a great interest in making arrangements for the celebration of the bicentenary anniversary of the foundation of the Worcester Infirmary, which is due to be held shortly. One of the Infirmary wards is dedicated to one of the founders, Bishop Maddox.

The colleague and friend from boyhood who wrote the above memoir adds: The death of Tom Bates has left a very great gap in the life of the city of Worcester and district and in the counsels of the Royal Infirmary. He had spent practically the whole of his life in Worcester and was undoubtedly a true citizen. The sympathy of all who knew him is extended to his widow, daughter, and two sons in their great loss. His younger son is now surgical registrar at Bart's in the E.M.S. Chest Unit. A memorial service held at Worcester Cathedral was attended by a very large number of people on Nov. 25.

The death of Dr. FRED PHILLIPS on Oct. 20 is reported from Boksburg, Transvaal. He was born in Newcastle-upon-Tyne in 1887, and from school he embarked upon a classical course, taking residence at Hatfield Hall, Durham, and ultimately attaining his M.A. degree of that university. Medicine

then attracting him, he graduated M.B., B.S. Dunelm through the Newcastle-upon-Tyne School of Medicine in 1912, subsequently serving as house-surgeon and resident medical officer at the Durham County Hospital. There he developed radiology as a specialty, and in that capacity took over to France one of the first mobile x-ray units during the early part of the last war. With the rank of captain R.A.M.C., T.F., he remained in x-ray work until the cessation of hostilities. General practice at Lanchester, Co. Durham, during the years 1921-2 failing to please him, he went to live at Parkstone, Dorset, whence he migrated to Buenos Aires and ultimately to South Africa. There an intractable surgical malady overtook him.

MR. WALTER HERMAN KIEP, honorary ophthalmic surgeon to the Bradford Eye and Ear Hospital, died suddenly at his home in Apsley Crescent, Bradford, on Nov. 21, at the age of 58. A native of Glasgow he studied medicine in that city, graduating M.B., Ch.B. (with commendation) in 1908. He served for a time as assistant surgeon to the Ophthalmic Institution of Glasgow and honorary oculist to the Royal Hospital for Sick Children. During the last war he held a commission in the R.A.M.C. as a specialist in ophthalmology at Malta 1915-19. After the war he was for a short time professor of ophthalmology in the Egyptian Government Medical School at Cairo. He went to Bradford twenty years ago, and in addition to his post at the Royal Eye and Ear Hospital served also as honorary consulting ophthalmic surgeon to the Victoria Hospital, Keighley, and the Hartley Hospital, Colne. Mr. Kiep was ophthalmic referee under the Workmen's Compensation Act, and had been president of the North of England Ophthalmological Society. He joined the B.M.A. in 1910.

We regret to announce the death in Edinburgh on Nov. 22 of Major JOHN GILMOUR, formerly president of the International Quarantine Board, Egypt, and for the past 15 months temporary inspector under the Cruelty to Animals Act. Born on Sept. 25, 1884, he was educated at George Watson's College and Edinburgh University, graduating M.B., Ch.B. in 1906, and taking the F.R.C.S. Ed. in 1909 after holding house appointments. He joined the R.A.M.C. in 1910 and served throughout the last war, being gazetted brevet major in 1918 after winning the Military Cross. He retired from the Army in the following year, and in 1929 became president of the International Quarantine Board at Alexandria. Major Gilmour held the Insignia of Grand Officer of the Order of the Nile and of the Order of Ismail; he was also a Commander of the Order of George I of Greece and a Chevalier of the Legion of Honour. He was created C.M.G. in 1934. He published a report on the sanitary conditions in Persia in 1924 and annual reports on the pilgrimage to the Hedjaz to the International Health Office, Paris, from 1928 to 1939. During this war he worked in the Department of Health for Scotland until his temporary appointment under the Home Office.

MR. GORDON WILSON THOMAS, consulting surgeon to the Clayton Hospital, Wakefield, died on Nov. 26. He was born at Llanelli on June 18, 1881, and was educated at the Friends' School, Bootham, York, leaving in 1898 to study medicine, first at Leeds and later at the London Hospital. He graduated M.B., B.S. Lond. in 1905 and took the F.R.C.S. Eng. in 1910 after four years in resident appointments at the General Infirmary at Leeds. Settling in practice at Wakefield he became senior honorary surgeon to the Clayton Hospital. Mr. Thomas was an active member of the Leeds and West Riding Medico-Chirurgical Society and held office as chairman of the Wakefield, Pontefract, and Castleford Division of the M.A. in 1930-2. When he retired from work on account of ill-health he made his home at Guildford.

By the death of Dr. LOUIS BEER the medical profession loses a really remarkable personality. Born in Amsterdam he was brought to his father's home in the Hampstead Road at the age of 6, and from that time till his death 73 years later he occupied the same house. In the early 'eighties he entered the Middlesex Hospital Medical School and had as fellow students Essex Wynter and John Bland-Sutton, the three becoming lifelong friends. Beer qualified in 1886 and carried on his work as a general practitioner till the day of his death. His gifts were exceptional. He was a most accomplished linguist and was reputed to be able to converse in seven European languages. His mother was of French extraction, and it was said, by those able to judge, that his mastery of the French language was superb. Owing to this ability he had a very extensive practice among foreign residents in all parts of London. His mind was built in a philosophic and logical mould, and I have rarely come across such an acute clinical observer or a more accurate diagnostician. It was a privilege and a pleasure to listen to

his preliminary description of the patient whom one was about to see. The salient features were emphasized and a lucid and brilliant picture of the case was presented with a simplicity and directness of language which were remarkable. His descriptions were so faultless that they might well serve as classic models of what clinical summaries should be. The effect produced on the listener was as if he were being shown a piece of sculpture, so clean and clear was the outline. Nor can I recall a single occasion on which I detected an error either of observation or in the logical deduction drawn from the data. Like most old physicians his diagnosis was based upon his knowledge of morbid anatomy, and curiously enough it was at a post-mortem examination that I first made his acquaintance 42 years ago. Practising in the neighbourhood, he frequently sent patients into the Middlesex Hospital, where, among the members of the hospital staff, he had a crowd of friends and admirers. His whole life was spent among his patients, and to them his passion will be irreparable. To poor and rich alike he was always the same. He found his reward in the quality of his work and in the confidence and devotion he inspired in his patients. I was a member of the British Medical Association and for seven years he held an appointment as clinical assistant to the St. Mary's Hospital for Women, gynaecology being a branch of medicine in which he was always interested. He died, as he would have wished to die, in harness. He was making an emergency call when he was stricken and the end came within a few hours. *Quis scit, an adjiciant hodiernae crastina summae tempora superi?*—C. E. LAKIN.
